1941

More important because far more common is the clinical picture mentioned as *subacute nephritis*, wet or nephrotic type. This group consists mostly of male patients, Hindus and Mohammedans, from 2 to 50 years of age, admitted as general anasarca, that is a bulging ascites, oedema of legs and frequently of the scrotum but very little—if any—puffiness of the face, sometimes a moderate double pleural effusion. The patients' history indicates an insidious onset of the swelling, a few months prior to admission and no definite complaints except general weakness and the discomfort due to the swelling, no headache or vomiting, and no sore throat. The clinical findings are uniform in all these cases: albumin 0.25 to 3 per cent, moderate or large numbers of every kind of cast, red cells present in all cases mostly ++ to +++, leucocytosis to a small or moderate amount, the concentration power usually reduced to a specific gravity of 1015 to 1018 and reaching 1024 only in one case, blood pressure was, in about half of these cases, increased between 135 and 160 with normal diastolic pressure, heart changes according to the pressure, fundal changes conspicuously absent except for 2 cases with some mild atherosclerotic changes, and blood urea from 28 to 40 mg. All these patients had a big spleen floating in the ascites, and in some of them protruding from the abdomen when the ascites had disappeared. The malarial infection showed different degrees of activity: none of this group was admitted with regular attacks. Parasites (BT rings) were present in a minority, malaria flocculation test was mostly positive and nearly every one of these cases had an occasional attack or rigor and fever during a longer lasting observation, never appearing again after anti-malarial treatment.

Instead of discussing the prognosis of this kind of subacute nephritis, it will be better to describe how they responded to treatment. Kept in bed, on a diet consisting of one pint of milk, one pint of buttermilk, half a pint of coffee and 8 ounces of bread or whole-wheat *chapati*, some of these patients passed much larger quantities of urine and chlorides, and lost weight from day to day without any additional treatment; e.g., a boy of 18, 30 pounds in 16 days, a Mohammedan of 40, 50 pounds in 5 weeks, and one of the rare female cases 22 pounds in 10 days. But the majority of this group did not respond to diet and rest alone; their weight remained constant or increased after a slight initial reduction, and neither diuretic mixture nor diuretin with caffeine succeeded in eliminating the retained water and salts. We tried indigenous drugs taking Chopra's invaluable experience as guide, we used *Bærhaavia diffusa* (*Punarnava*) and *Herpestis monniera* (*gokhru*) extracts, supplied by three different Indian firms, we did not get a satisfactory result, whether we tried each of these drugs separately or both of them combined, whether we gave the

dose prescribed or increased it up to twice this amount. Dr. Subbaramiah suggested the use of *Cynodon dactylon*, a grass growing locally and frequently used as a popular diuretic; we gave up to 12 drachms of a concentrated alcoholic extract per day. The plant grown during the rains had in some cases a good effect, not afterwards when the grass became dry. Mercurial diuretics are contra-indicated because of the glomerular lesion, though they produce sometimes a good diuresis for a day or two. It was a most unsatisfactory solution of this therapeutic problem to tap the ascites once in 10 or 14 days and to wait helplessly until the peritoneal cavity filled again.

The most simple solution was found as we started to use quinine in full dose without delay in all splenomegalic cases of subacute nephritis in spite of absence of fever as soon as the weight became constant for 3 days or began to rise; the table shows a typical weight chart of one of these cases.

Such a therapeutic effect makes the diagnosis 'malarial nephritis' most probable, even for those who do not believe that the regular co-existence of malarial infection and this type of renal anasarca is sufficient to recognize the aetiological rôle of the malarial infection. Slightly less satisfying than the diuretic effect is the healing effect of anti-malarial treatment, estimated by the improvement of pathological findings in the urine. In some of our cases albumin, red cells and casts disappeared entirely from the urine as in the case whose weight chart is reproduced in the table. This patient showed on admission a high albuminuria, plenty of red cells and every field of the sediment crowded with granular casts; 3 weeks later—after a full course of quinine and no other treatment—the most carefully repeated search did not show one single red cell or cast, and only faint traces of albumin. But not every case reacts like that; several of these left the hospital with red cells still present, casts definitely less but not entirely absent, albuminuria reduced though not altogether cured; the increased blood pressure was no more rapidly improved than strict diet and rest usually achieve. Taken altogether it seems almost certain that by far the most of these renal anasarca cases are due to malarial nephritis. It seems improbable that our cases belong to the same clinical group as those accompanying or following quartan malaria, described by Watson (1904), Clarke (1912), Goldie (Palestine), Manson-Bahr and Maybury (1927), Carothers (East Africa), Surbeck (Sumatra), and Giglioli (Br. Guiana), who found in a small percentage malignant tertian infections. Quartan malaria is a rarity here; only one of our subacute nephritis cases gave a history which made quartan fever probable. Owing to the chronicity and low activity of the malarial infection in most of our cases, parasites have been found in a minority of them only; but these

parasites were *Plasmodium vivax* never *P. malariae*.

To explain how malaria causes nephritis is theoretically possible only but it seems most probable that the kidney damage is an allergic process, due to the sensitization to 'foreign' proteins belonging either to the parasites or derived from destroyed body-tissue; that would explain why only in a small fraction of all malarial infections an acute or subacute nephritis develops, as a certain constitutional type would be the necessary condition for the appearance of this 'kidney-hypersensitivity'.

(c) *Ancylostomiasis*.—Hookworm infection is by far the most frequent cause of general anasarca in Mysore. To study its manifestations, its prognosis and treatment is therefore most interesting especially as apparently nowhere else—neither in Iraq nor in America nor even as near as the Madras Presidency, are such

desperate looking cases of hookworm disease to be found as we see here every day.

The incidence of infection is amazingly high, at least 60 per cent of our hospital patients pass hookworm eggs—men and women are both heavily infected, the ryot far more of course than the city dweller. The clinical picture of general anasarca due to hookworm disease is so uniform that the diagnosis is usually established as soon as one sees the patient. The face waxy pale presenting a greyish hue and puffy, the eyelids swollen as in the worst cases of acute nephritis, tongue and palate looking like grey paper, a mighty ascites containing 25 pints and more of straw-coloured transudate, nearly free of protein, specific gravity about 1006; maximal swelling of legs and scrotum completes the external picture. The pulse rate is high, the heart enlarged to both sides to such an extent that it seems to touch both lateral chest walls—

the largest hearts one can see are hookworm hearts. The configuration is mitral, but such an enlargement is only seen, when due to valvular disease, in combined mitral-tricuspidal-aortic lesions; a harsh systolic murmur is always present over all the valves, its maximum usually nearer the pulmonary than the mitral area and in many cases well conducted outwards up to the posterior axillary line, just as described in textbooks as proving an organic mitral disease. To make the imitation of a double mitral still more perfect, a systolic thrill is sometimes distinctly palpable. And yet the differential diagnosis has to be made and is not difficult; a mitral disease giving rise to such a degree of anasarca is highly dyspnoeic (orthopnoeic), struggling for air, showing all signs of lung congestion, a huge tender liver, icteric or subicteric sclerae, cyanosis of lips and finger nails, a normal or increased haemoglobin content, a normal diastolic pressure, and signs of kidney congestion in the urine. Quite different are behaviour and signs in hookworm anasarca. The patients are lying quietly flat on their back or on one side with a characteristic apathetic expression, sometimes even covering the head with the blanket, hardly answering questions; lung congestion is mostly absent, the liver slightly enlarged, if at all, and not tender, and no subicterus present, if not due to malarial haemolysis, cyanosis is absent. The haemoglobin content is the lowest recorded in living beings, we guessed values of about 8 per cent and in many cases Sahli's haemoglobinometer shows 11 or 12 per cent on admission. The systolic pressure is normal or slightly diminished like in mitral disease, but the diastolic pressure is distinctly low, usually between 65 and 50, slowly increasing with general improvement. Very important for the diagnosis from congestive heart-failure, as well as from acute nephritis or nephrosis, is the urine examination which does not show either albumin or any pathological sediment; even traces of albumin, a few red cells or occasional casts are proof of a complication, as far as my experience goes, and are never to be found in pure hookworm disease.

Discussion.—It is all important, it is often literally a question of life or death, to find out the cause of general anasarca in every individual case; when we treat a congestive heart-failure as ancylostomiasis, because the patient passes hookworm eggs, or when we treat a hookworm anasarca as a heart-failure, because the heart shows all signs of a valvular lesion, we won't save the patient's life. In these hookworm cases exists only one line of rational treatment: to improve the blood condition so far that carbon-tetrachloride or tetrachlorethylene can be given without risk. Though hookworm anaemia is known as a typical microcytic-hypochromic anaemia that simply has to improve quickly on administration of sufficient doses of ferrous iron, some of our patients do not follow this rule. We give in every case 90 grains of freshly

prepared Blaud's pills per day and the effect is practically always a quick improvement from Sahli 12 to 18 or 20, but from this level upwards the blood improvement progresses quickly and satisfactorily only in the majority of our cases, not in all of them. A minority remains that requires crude liver extract for further improvement; these cases are characterized by a comparatively high colour index of about 0.8, whereas the simple iron deficiency anaemias have an index of about 0.35 to 0.5. The higher index is not due to a higher haemoglobin content, but to a still more reduced red cell count; figures of 0.7 million red cells and haemoglobin 12 per cent are typical for the liver-requiring cases. Though the general condition improves surprisingly quickly under this treatment, accompanied by plenty of milk, wheat chapatis, rice polishing or marmite, ascites and oedema require their own treatment. The patients and we—always in need of beds—cannot wait until the ascites begins slowly to vanish 6 to 8 weeks after admission when the hypoproteinæmia is so far repaired that the colloid osmotic pressure of the blood plasma rises to a normal level. We have to speed up the fluid elimination by using diuretics.

The same difficulties arise again as in the nephritis group; mercurial diuretics are dangerous as long as a substantial anaemia persists producing diarrhoea instead of diuresis; in our first publication on the diuretic action of novasurol (1919-1920) Saxl and myself warned against its use in anaemic and cachectic conditions; *gokhru*, *punarnava*, *mistura diuretica*, caffeine and diuretin have no more effect in hookworm anasarca than in the malarial nephritis; cynodon extract was in several cases quite useful but after the rains stopped, it apparently lost its diuretic qualities; disappointing also was apocynum. We had to try again and again until we found that the combined use of ammonium chloride grs. xx, calcium chloride grs. v, five times a day and urea drachms v, t.d.s., has the best diuretic effect though in some cases diarrhoea compels one to stop this treatment for 2 to 3 days. In most of our cases 3 weeks of this combined anti-anaemic and diuretic treatment improve the general condition so far that, at a haemoglobin level of 35 to 40 per cent, the usual anti-helminthic treatment may be applied without any bad by-effect, yielding innumerable hookworms (*Necator americanus*); rarely a patient is discharged unless 3 motions examined on alternate days have been found free of hookworm eggs.

Conclusion

Summarizing one has to say: general anasarca in our hospital cases is due to heart-failure, nephritis, or ancylostomiasis. The heart-failure is mostly a consequence of valvular lesions or of essential hypertension, a condition remarkably frequent among Brahmins, living for many

HYDROTHERAPY IN TYPHOID FEVER

By G. R. McROBERT, M.B., F.R.C.P.
LIEUTENANT-COLONEL, I.M.S.

*Professor of Medicine, Madras Medical College, and
Senior Physician, Madras General Hospital*

IT is generally recognized that the administration of large quantities of fluid has a beneficial effect in the treatment of most specific fevers.

In enteric fever in particular, it is most important to maintain the fluid intake at a high level.

With a large number of severe cases of enteric in a busy ward, it is very difficult to ensure that semi-conscious patients imbibe a sufficient quantity of water, even if arrangements are made for suitable containers to be at hand.

During the past two years I have been using continuous rectal drip saline in toxic and semi-conscious enteric fever cases, and I am satisfied that this measure helps in reducing toxæmia and in ensuring a continuous supply of fluid which could not be guaranteed by any other nursing method.

The virulence of enteric fever in this country seems to vary greatly from year to year and from one outbreak to another, but after long experience of the disease I have come to the conclusion that continuous rectal drip provides a valuable weapon in combating the severe toxæmia which one meets so often. In this I am supported by senior nursing sisters with many years of experience.

In the warm climate of south India we have, as a rule, no difficulty in administering by the rectal route 6 pints of normal saline in 24 hours, i.e., an hourly rate of 5 ounces. Even in patients with diarrhoea considerable absorption takes place.

A soft catheter should be used and introduced just within the rectum. A glass visible dripper

centuries on strictest vegetarian food. The nephritis, either an acute or subacute glomerulo-nephritis, is frequently so closely connected with malarial infection that many of the cases seem to belong to the interesting clinical entity, 'malarial nephritis'. By far the largest number of our anasarca cases are due to hook-worm infection. Regarding the treatment—the heart-failure cases respond very well to digitalis and mercurial diuretics; the malarial nephritis to milk diet and rest in bed, and, if water retention still persists, quinine is the best diuretic; ascites and œdema in ancylostomiasis respond best to ammonium chloride and urea.

My thanks are due to the Government of Mysore, whose kindness gave me the opportunity to do here clinical work, and to my staff whose ideal co-operation made these investigations possible.

INTRAPARTUM UTERINE RUPTURE

(WITH A REPORT ON FOUR CASES)

By H. S. WATERS, F.R.C.S. (Eng.), M.R.C.O.G.
MAJOR, I.M.S.

Professor of Midwifery and Gynaecology, Grant Medical College, and Specialist in Obstetrics with Gynaecology, Bai Mollibai and Petit Hospitals, Bombay

THIS accident, which is one of the most serious in obstetrics, is fortunately rare. Davis (1927) gives an incidence of 1 in 810 labours in 184 cases from the records of the New York Lying-in Hospital. Figures for India are not available, but three cases occurred in 2,016 deliveries at the Sassoon Hospital, Poona, in the last 2 years—an incidence of 1: 672. Both hospitals deal largely with cases of difficult labour, whereas Shears (1924) referring to all labours gives the incidence as 1 in 3,500.

It is, however, questionable whether rupture does not actually occur more often than is generally supposed, particularly in countries like India where labour often takes place many miles from medical aid, and where pelvic deformities are common.

The usual textbook description of intrapartum rupture of the uterus states that it is predisposed to by any condition which may have weakened the uterine wall. Previous Cæsarean section or myomectomy, adherent placenta, and too vigorous curettage may be instances, and debility and too frequent child-bearing may be other predisposing causes.

The actual rupture is brought about spontaneously (as in neglected obstructed labours due to malpresentations or pelvic contraction) or by the manipulations necessary to deal with these conditions, such as version or eranotomy.

The cases (less common in India) where rupture takes place through a weak operation scar of the uterine wall are omitted from the following description of uterine rupture. The more common type in this country takes place through a thinned-out lower uterine segment, and (again according to the textbooks) is accompanied by such dramatic symptoms and signs that the diagnosis could hardly be missed.

The story is usually as follows:—During a long and tedious second stage of labour the uterine contractions get more and more frequent and painful, and the intervals between them become progressively shorter. The whole

(Continued from previous column)

is necessary but one can easily be improvised from an old-fashioned fountain pen filler.

There seems to be no advantage in adding glucose to the rectal saline.

During the war of 1914-18, it was found in Mesopotamia that intravenous normal saline reduced the toxæmia in cases of louse typhus. I recommend the use of continuous rectal saline to any who may come into contact with that disease also.

uterus is very tender and the foetal parts hard to make out. The retraction ring of Bandl can be seen or felt above the symphysis and even rising up towards the umbilical region, while the round ligaments too may be felt as tense cords.

Suddenly, at the acme of a pain, the patient may feel that something has given way inside her and cry out with the pain. After that she has great relief and all pains cease. Signs of shock and internal haemorrhage soon supervene.

On examination at this stage the foetal parts may be very easily felt, if the child has escaped completely through the rent. Otherwise the uterus feels irregular in shape but not so hard and tense as before. On vaginal examination, there is a certain amount of bleeding and the presenting part is found to have receded somewhat and to be no longer jammed in the pelvis. The actual tear in the uterine wall can sometimes be felt.

Such a picture may be true of the majority of ruptures occurring in labour, but, as the following cases show, the diagnosis is not by any means always so easy.

In the first place, rupture may occur when the patient is anaesthetized for some obstetrical operation, in which case the rupture may not be recognized. When the patient dies later after delivery, her death is returned as due to 'obstetric shock' or 'haemorrhage', unless a post-mortem examination is made.

Further the rupture may be only a small extra-peritoneal one not involving big vessels. Such patients may recover after delivery without the true nature of the condition being recognized. The result would be a residual scar which might yield in a subsequent labour.

Even if the classical signs of impending rupture have been present and have been followed by rupture, no trained observer may have been there to see them, and the patient may die before she can be brought to hospital.

There would seem also to be another type of case in which 'silent' rupture takes place without dramatic symptoms. The patient may have had several normal deliveries, and no marked disproportion or malpresentation can be found. Yet gradual rupture occurs, the rent possibly extending slowly with each pain. Eventually pains become weaker and cease while signs of collapse gradually supervene for no apparent reason. There is little to draw attention to the very serious accident that has occurred.

Such cases are probably due to a uterine muscle which has been weakened, thinned and stretched by rapidly succeeding pregnancies and the general debility of the patient. The diagnosis of rupture is likely to be missed in such cases, though they are not uncommon.

The following cases illustrate some of the above points :—

Case 1.—A 2nd para, aged 24 years, who had had a forceps delivery five years ago with a stillborn child, was admitted at 5 a.m. on the 16th July, 1939, with a

history of prolonged labour and early rupture of the membranes. She had not attended any antenatal clinic.

On examination the uterus was contracting strongly, the foetal head not engaged and lying in the 1st vertex position; no foetal heart sounds heard; os two fingers dilated and presenting part high. Promontory easily felt.

It was decided to wait for dilatation of the cervix and then deliver by craniotomy.

12.30 p.m. Patient getting distressed: os four fingers dilated with oedematous anterior lip; marked caput.

Under general anaesthesia the head was perforated, four long Kocher's forceps were applied to the scalp round the perforation, and one pound weight tied to their handles. Brain matter came out freely.

Following the anaesthetic, all uterine contractions ceased, in spite of pituitrin in small doses twice repeated. Prontosil 10 c.c.m. was given about 4.30 p.m. as a prophylactic, and repeated periodically.

By 12.30 a.m. on 17th July, 1939, the patient was exhausted, pulse 100, temperature 100, abdomen distended and tender, os very oedematous and loose, though nearly fully dilated, uterine contractions feeble and presenting part still high.

Under general anaesthesia the doctor on duty removed the Kocher's forceps and extracted the child with a cephalotribe with some difficulty at 1.30 a.m. The placenta had not appeared by 2.45 a.m., so it was expressed by Crede's method, and a hot intra-uterine douche given. There was very little bleeding throughout.

Subsequent progress.—The patient was given altogether five injections of prontosil and soluseptasinc and also sulphonamide tablets 2 q.i.d. for five days with intravenous glucose.

Her abdomen remained very tender and inclined to be distended, and her condition was never good. Her temperature varied between 99 to 99.6 for the next four days. She vomited twice and her pulse was feeble and thready.

On the 19th July, 1939, the peritoneum was drained through a supra-pubic incision under local anaesthesia. Some gas with reddish-brown fluid escaped. This was sent for culture, and meanwhile 20 c.c.m. of anti-gas-gangrene serum was given.

On the 20th July, 1939, the constipation had given way to a terminal diarrhoea—4 to 5 motions per day. She died on the 22nd July, 1939, with the temperature rising to 104°F. and respirations 48 just before death. This was 6½ days after admission.

Post-mortem examination.—Dr. A. J. Naronha showed about ¼ pint of reddish-brown fluid and old blood clots in the pelvis. The uterus was 5½ inches long and there was a recent tear in the anterior uterine wall about 2½ inches long running upwards and to the left above the peritoneal reflection on the bladder.

The uterine wall showed a few areas of hemorrhage; endometrium septic but not thickened. Peritoneum not markedly inflamed.

Culture of the peritoneal fluid produced no anaerobes.

There were areas of consolidation in the lungs, but no obvious broncho-pneumonia.

Comment.—It is difficult to make out exactly when rupture occurred, but it seems probable that the extraction with the cephalotribe through an oedematous cervix with thinned-out lower uterine segment may have caused the actual rupture. As the patient was under an anaesthetic and the uterus not contracting strongly, the clinical signs of rupture were never present, and the condition was only found post mortem.

The reddish fluid removed on draining the peritoneum might have made one suspect some intraperitoneal injury, but the accompanying gas made one think of an anaerobic infection with gas-forming organisms.

Case 2.—A 7th para, farmer's wife, aged about 35 years, was admitted in labour on the 16th January, 1940, at 12-10 a.m. Her previous six deliveries had been normal full-term labours and she had not attended any ante-natal clinic.

On examination there was nothing remarkable noted. The child was in the vertex-I position, head engaging but not well flexed.

Membranes ruptured at 2-15 a.m. when the os was 3/5 dilated. Foetal heart 136 per minute.

At 8 a.m. she was seen by the resident medical officer when the foetal heart sounds were absent and the patient's pulse feeble.

When I saw her at 8-30 her pulse was 144; os 3 fingers dilated and the foetal head was high up and floating. The uterus was not contracting well, and what was thought to be placental tissue could be felt anteriorly. There was considerable bleeding on examination, and placenta praevia was diagnosed.

Under light general anaesthesia and novocain infiltration, the abdomen was opened and the child, placenta and membranes were found lying free amongst the intestines, and were removed. There was a tear of the antero-lateral wall of the uterus extending into the cervix, and it was this tear that had probably been mistaken for placental tissue *per vaginam*. The pelvis was not noticeably contracted.

Subtotal hysterectomy was rapidly carried out followed by the usual post-operative treatment for shock. No compatible blood for transfusion was available.

Subsequent progress.—The patient rallied well, apart from offensive lochia and fever up to 100° for the first six days and she left hospital on the 22nd day.

Comment.—Rupture must have occurred early on the 16th January, 1940, the day of admission, without exciting the notice of patient or nurses—the 'silent' type of rupture. Even when seen at 8-30 a.m. she was thought to be a case of placenta praevia, though the head which had previously been reported as engaging was now high up and floating. Luckily operative treatment was carried out and the true condition dealt with.

The cause of the rupture in this case was probably degenerative changes in the uterine wall following repeated pregnancies and possibly sepsis. There had been no intra-vaginal manipulations as far as could be discovered, apart from vaginal examinations in hospital.

Case 3.—A 6th para, aged 30 years, wife of a tailor, was admitted in labour on the 16th November, 1939, at 10 a.m. Her first three children were normal full-term deliveries. Fourth child—transverse presentation and stillborn. Fifth child—forceps delivery in hospital, living, aged 1½ years.

She had been having pains for three days. On admission her condition was good. Child in vertex-I position, head floating, but could be made to engage. Uterine contractions good and foetal heart normal.

Progress.—11-50 a.m. Membranes ruptured. Os 2/5 dilated. 3-45 p.m. child passing meconium. Head engaged. Os fully dilated.

Forceps then applied under general anaesthesia by the medical officer on duty, without success.

On examination at 5-30 p.m. one could feel the foetal parts very easily just beneath the abdominal wall. No uterine contractions. Foetal heart sounds absent. Child appeared to be still in the first-vertex position, but an ill-defined swelling could be felt to the right. The head was still above the brim. Mother's pulse 90 per minute.

Per vaginam.—Dark blood escaping. Cord prolapsed and not pulsating. Presenting part not felt.

Ruptured uterus was diagnosed.

Operation.—Under local and general anaesthesia the abdomen was opened and the child and membranes and placenta were found loose in the abdominal cavity, and were removed. The tear in the uterus extended from the anterior part of the lower uterine segment upwards and to the left. There was very little blood in the peritoneal cavity.

The pelvis had well-marked pectenoid eminences and promontory of the sacrum.

Subtotal hysterectomy was carried out and the patient did very well. She had a rigor and fever up to 100°F. on the first day (? due to saline infusion) and later a mild bronchitis but left hospital 26 days after admission.

Comment.—Rupture in this case must have occurred during the 'failed-forceps' operation under anaesthesia. The notes state that the 'head was fixed and abdomen very tense' at that time. This was only three hours or so after the os was only 2/5 dilated, so that to rupture so early in labour it is possible that the uterine wall itself was not normal. Certainly the patient had not been allowed to linger on in obstructed labour hour after hour.

The records of the Bai Motlibai Hospital show only one case of ruptured uterus as having occurred in the last four years and I am indebted to Dr. V. N. Shirodkar for permission to publish the notes of this case.

Case 4.—The patient was a 3rd para, aged 34 years, who had had two stillborn children previously, following otherwise normal labours. The last one was one year ago. Her general condition was 'poorly'. Her Wassermann reaction was negative during her attendance at the ante-natal department. She had some uterine prolapse in the early months, for which a pessary had been fitted.

On admission on the 6th June, 1940, at 11-45 p.m. she was full-term and in labour. Child in vertex-I position; head engaged, but foetal heart slow and feeble.

Her measurements were 10 inches, 9 inches, and 7 inches. Her pulse rate 120. No uterine contractions were present, and liquor amnii was draining from the vagina.

Per vaginam.—The os was four fingers dilated and a large 'caput' could be felt.

At 6 a.m. on 7th June, 1940, the patient vomited twice. Her pulse was now 136 and of poor volume; upper abdomen distended; no pains felt. The patient appeared cyanosed.

She was given intravenous glucose and coramine and also inhalations of oxygen, but died at 6-30 a.m.

Post-mortem examination by Dr. P. V. Gharpure.—'On opening the abdomen a large amount of blood and blood clots came out. The foetus was found free in the peritoneal cavity, head in the pelvis. Uterus contracted and lying to the left of and behind the foetus. The contracted uterus held within it the greater part of the placenta. There was a tear of the right side of the uterus in the lower uterine segment extending from the supravaginal cervix to the ovarian ligament and involving the broad ligament'.

Comment.—This seems to have been a typical case of 'silent' rupture, without any dramatic symptoms and signs to attract the attention of those looking after the patient. She never got the severe pains usually described as associated with rupture of the uterus, neither was there any manipulative interference or

HIDDEN SEPSIS IN THE PALATINE TONSILS

By F. H. WHYTE, M.B., M.CH., F.R.C.S.I.
LIEUTENANT-COLONEL, I.M.S.

Civil Surgeon, New Delhi and Simla West

Introductory.—Anything that is hidden has always a certain interest which may grow as we get indications of its location and nature. We spend much of our time in looking for foci of infection, and their discovery and eradication often bring most gratifying results; conversely, overlooked foci produce many of the tragic and irreparable conditions that we frequently see in general practice. I refer to advanced cases of arthritis, cardiovascular disease, and patients with general deterioration of function and structure, caused apparently by months or even years of intoxication, or by the direct assault of germs lurking in concealed nests of infection.

Recent revelations have prompted me to devise an instrument to assist exploration for the hidden dangers found in the tonsils, and to write this article to review the position generally.

Tonsil speculum and squeezer

The instrument is simply a useful tongue depressor with knobs on one end to act as tonsil squeezers. A glance at the sketch conveys its primary uses—to hold down the tongue and at the same time express pus from the supratonsillar fossæ and crypts by pressure along the anterior pillars.

This tonsil speculum, in adult and children's sizes, has been made for me by the kind co-

(Continued from previous page)

anaesthesia in her case. A microscopical examination of the uterine muscle might possibly have shown some defect to account for the rupture in this case.

Summary

1. Four cases of rupture of the uterus in labour are reported.

2. Attention is drawn to the difficulty in diagnosis in many of these cases. Out of the four cases only one was definitely and correctly diagnosed before operation or post-mortem examination.

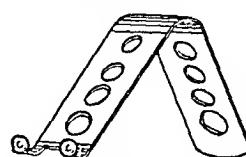

3. It seems probable that the condition is missed more frequently than one would suppose, particularly in the absence of post-mortem examinations on cases dying of shock and haemorrhage.

4. It is suggested that the textbook descriptions of rupture of the uterus should be supplemented by a description of the 'silent' type of rupture here described.

operation of Messrs. Allibhoy Valljee & Sons*. The only criticism I would make on these models is that the knobs should be placed a little more laterally on the necks. I have also to thank Messrs. Down Bros., London, for an earlier pattern, excellent in every way except that the 'ears' were too sharp.

Author's tonsil speculum and squeezer.

In practice, I find this combined tongue depressor and tonsil squeezer most efficient and simple to use. It is easy to carry around, does not frighten the patient, and the necessary firm pressure does not hurt. The handle end serves as an ordinary tongue depressor. Many methods of examining the tonsils involve the use of a head light and both hands for the introduction of special single-functioned instruments which are cumbersome, alarming, and liable to produce that facile reflex which may disturb the patient's latest meal. There are some patients who are most intolerant of any instrumental examination of the throat; for these considerable patience is required and it is found if they practise mouth-breathing for a few minutes and fully extend their chins, one can usually manage.

Textbooks commonly recommend the pressure of a tongue depressor, with or without a second one to depress the tongue, or the end of a spoon, instruments that are often much too sharp and clumsy. A knob of cotton-wool in artery forceps is more satisfactory.

There is nothing at all new, of course, about pressing the anterior pillars to reveal pus. My hypothesis is that it is not done often enough or efficiently enough, and that simplicity of equipment and technique are here, as everywhere, of primary importance. Similar instruments such as those of Hartman, Tilley, Howarth, Way, etc., and the suction tubes of Bier and Eve require, as a rule, the assistance of a tongue depressor and head light and are special equipment usually not available, and which in use are associated with some fuss which is seldom appreciated by children, or nervous patients.

This speculum not only reveals pus but also supplies information as to mobility, capsulitis, the size and depth of the tonsils, and the nature and extent of their folds which helps in deciding the nature of the anaesthetic and operation if such are necessary.

In considering the tonsils for pathological changes an incorrect diagnosis is encouraged by

*The Alvi Works, Multan Cantonment, can supply a certain demand at a very reasonable cost of Rs. 5 each.

a healthy appearance of the throat, the small superficial size of the tonsils, the absence of injection of the anterior pillars, or a negative history of repeated sore throat or tonsillitis, and if an attempt is made to press out pus some improvised and unsatisfactory method is adopted. One does not always care to ask a tired parent to chase downstairs for the usual dessertspoon or to refuse the services of an ornamental one which may be offered on return. I have occasionally used the handle of a tooth brush but more often than not they are too pointed.

It would be well always to bear in mind that a perfectly healthy looking tonsil may contain much pus, particularly in young adults and often enough in children, and that no examination is satisfactory unless firm pressure is applied to the anterior pillars. To miss a quiet focus of infection in the gall bladder, kidney, appendix or a nasal sinus, is certainly excusable, but less so when overlooked in the superficial and more common sites. Quite recently of three patients admitted to adjoining beds, all with serious disease of heart or kidneys, it was found that although all three had normal looking tonsils each had also gross lacunar sepsis.

It is regrettable to find so much diversity of advice being given concerning treatment and the indications for the removal of tonsils. On the one hand, there is the operator who advocates the removal of practically all the tonsils he sees, and on the other, the practitioner who only uses direct inspection and unless he observes some striking abnormality proceeds no further. In addition there are various methods of active treatment in common use which are at best improvisations or temporary in effect, and liable to promote a sense of security that is false or to lead to ultimate disaster unless applied only in the case of very selected patients who can be depended upon for regular examination. This diversity is largely due to the methods used in the examination of the patient's throat.

Tonsillectomy

A short general survey may, I hope, assist some to clarify their clinical opinions on a subject liable to wide divergence of view.

Considering patients who have been examined with reference to the condition of their throats, one is inclined to believe that, though many useful tonsils have been removed in childhood, it is certain that many most dangerous ones have been overlooked, more particularly in young adults. The early effects in each case being insidious rather than robustly manifest, both the lay and professional reactions to the results tend to remain in abeyance.

Disregard for textbooks and careless examination are commonly found in company, yet I am sure imperfect examination rather than deficient academic information in the case of tonsillar troubles is the cause more largely responsible for those adverse effects on heart, joint, kidney,

lymph glands, lungs and even brain, which are so frequently cases of chronic toxic absorption from overlooked tonsillar sepsis. It is poor ground for gratification to feel that there are fewer tragedies from mass tonsillectomy than from misguided conservatism of septic tonsils following defective or careless examination.

It is surprising that a tonsillectomy inconsiderately recommended but never done is more liable to lead to fractious and uncomplimentary remarks from an irate parent or patient than the most unwarranted inaction in the case where dangerous tonsils had been exonerated though causing months or years of damage, and I have had more often to palliate such a criticism than to defend a conservative opinion where chronic lacunar sepsis had seriously or indeed permanently injured a patient's health.

The modern onslaught, which suggests a propaganda that the tonsils are an error of nature, has misled a large section of the public who put up their children for tonsillectomy as a matter of course and they feel disgruntled if their doctor differs with this view. In contrast to the majority, there are some who are difficult to convince that operation is the only way to safety. It is usually easy to demonstrate clearly or explain why tonsils require removal, a course which helps all concerned.

In India especially, where patients frequently go from one practitioner to another in an endeavour to obtain a majority opinion, it is a pity we could not all give the same advice, and since the supra-tonsillar fossa may take anything from a few days to some weeks to refill, it would be well to enquire when and how the last examination had been conducted.

The behaviour of the supra-tonsillar recess, or more correctly the intra-tonsillar fossa or lacuna magna, is the greatest source of error unless properly investigated. This inner or posterior end of the second branchial cleft is one of the few developmental remnants that is capable, in our stage of evolution at least, of doing much harm. It is the biggest culture and filter tube in the tonsillar immunizing scheme, but unfortunately too often refuses to empty or renew its contents, as it is situated in the upper end of an almost solid gland which is frequently hardened by fibrosis and uninfluenced by the pressure of deglutition, and has its mouth often covered by the anterior palatine fold or plica superior. The crypts are not so liable to this dysfunction, and less frequently can pus, either fluid or inspissated, be expressed from them in quantity and they yield much more freely to medical measures. The material seen bursting out of the crypts during removal of 'enlarged' tonsils, by the guillotine, is usually perfectly healthy and useful lymphoid tissue.

The following is a list of remarks for consideration before recommending tonsillectomy :—

- I. Size.—Parenchymatous enlargement is usually a contra-indication unless so big as to

cause dysphagia or dyspnœa (I have only seen one case with dyspnœa, the patient was an undersized girl, aged 14 years). It would be an error to interfere with the physiological enlargement seen commonly in children of 4 to 6 years. Small tonsils may be much more dangerous than enlarged ones, fibrosis making them contract.

2. Sepsis.—Is it superficial, cryptic or lacunar, acute or chronic? Chronic lacunar sepsis with the intra-tonsillar fossa involved is the commonest indication for tonsillectomy. Some suggest that inspissated pus in the lacuna is harmless, but it cannot often remain permanently inspissated since liquefaction is one of the common properties of bacterial activity.

(a) The indications in chronic sepsis are more frequently to prevent or remedy remote effects rather than local discomforts, and cover the wide range of lesions due to chronic septic absorption.

(b) Recurrent attacks of superficial tonsilitis suggest operation especially when associated with local and less remote complications such as ear trouble, laryngitis, tracheitis, bronchitis or dyspepsia; the acute features being first encouraged to subside. Removal under this heading will also prevent the development of chronic lacunar sepsis and its acute manifestation—quinsy.

(c) Acute inflammation when simple or associated with the organisms or syphilis or Vineent's angina is best treated to begin with by medical measures.

3. Age of the patient.—The extremes of age require careful study. From 7 to 10 years is about the most suitable age for tonsillectomy, during this period the indications need not be so obvious as at other ages.

4. When faced with one of the long list of conditions reputedly due to or aggravated by septic absorption, the state of the tonsils and history of sore throats should be carefully investigated. Recently, the tonsils have again been incriminated as the direct origin of streptococci attacking the valves of the heart. The tonsils are often the portals of entry of tuberculous infection, which is first noticed as an adenitis of the glands of the neck. The presence of arthritis, fibrositis, neuritis, peptic ulcer, diabetes, anaemia, iridocyclitis and many others, invite examination of the tonsils and perhaps their removal at a time indicated by the general condition of the patient.

5. Mobility.—Diminished mobility usually indicates chronic sepsis with capsulitis and shortened lymph vessels. Closely wrapped pillars and plicæ diminish mobility, so also does opening the mouth to its full extent.

6. Prophylaxis of certain diseases.—Tonsillectomy is useful against diphtheria and in curing carriers, but is not of much use in influencing acute rheumatism unless performed very early. Unhealthy tonsils should be removed early in pregnancy and before operations on the

stomach and air passages when urgency is not important.

7. Intra-tonsillar calculi.—These usually indicate tonsillectomy.

8. Chemotherapy.—The prontosil group of drugs are most useful in getting over the acute phases of inflammation but for the deep chronic infections, their use has limitations and cannot much influence the ultimate necessity of tonsillectomy.

9. Carcinoma or sarcoma.—When these are early and confined to the tonsil, dissection is sound, though radium alone is also used in malignancy. The size of the tumour is less important than its radio-sensitivity. Immediately the new growth extends beyond the capsule, the whole outlook changes for the worse and diathermy or radium or both are the only options.

A long list of 'T's and A's' would not appear to be a very carefully considered programme in many parts of the world. Especially in young children below the age of 6 or 7, one or other should be spared. Damp climate, city life, defective diet and hereditary influences, aetiological factors in excessive adenoid growth, do not always produce the same effects. (A very noticeable feature of general surgical conditions in India is the constant variation from place to place, a variation which must depend on factors more obscure than the usual aetiological causes of disease can explain.)

Removal and recurrences

Dissection is the method of greatest precision but it is classed as a major operation and requires a more specialized anaesthetic. The objections to the guillotine are that few cases are really suitable and that its proper use is difficult. When the tonsils are mobile and prominent (or a short anaesthetic is desirable) the guillotine is certainly the method of choice as under these conditions slicing and recurrence should be almost as infrequent as after dissection.

These recurrences of tonsillar tissue though they seldom give rise to more than local trouble, unless remnants of fossæ are left behind, are a source of complaint and make a popular subject of topical conversation. An elementary explanation on the cause of recurrence without special reference to the nature of Waldeyer's ring usually leads to the naive confession—'Oh, I never knew that'. This admission, given in good faith, is made as if page 44 of the *British Encyclopædia of Medical Practice*, Vol. 12, was the only one that had been inadvertently overturned. Recurrences usually appear at the lingual end (where actual lymphoid tissue has to be cut through) and can follow dissection as well as the guillotine operation. I recently had the opportunity to mitigate the disappointment of a patient who had been operated on twice by a well-known London specialist.

AN INQUIRY INTO THE INCIDENCE OF PORPHYRINURIA

By A. D. JOSEPH, M.B., B.S.

(Assisted by V. P. GEORGE, B.Sc.)

(From the Miraj Medical Centre, Miraj, S. M. C.)

It was recently recognized that porphyrinuria is an integral part of the pellagra syndrome and its presence can be used as an early objective test. It has been the observation of the medical consultants of the Miraj Medical Centre that larval forms of pellagra are occasionally encountered among the patients that pass through our clinic. In addition many cases are seen which present one or more manifestations of pre-pellagrous state, such as glossitis, angular stomatitis, atrophic condition of the lips, hyperpigmented patches, especially over the buccal mucosa, cramping pains in abdominal and leg muscles, dermatitis, dry scaly atrophic condition of the skin, paraesthesia, chronic diarrhoea, fibrillary twitchings of muscles, etc. In most of these cases, we have observed that clinical improvement occurs on the administration of nicotinic acid and yeast, in adequate dosage.

This article is the result of an attempt to place our observations on a biochemical basis taking advantage of the fact that porphyrinuria is an accompaniment of the pellagrous, or pre-pellagrous state. The work of Beckh, Ellinger and Spies (1937) has shown beyond doubt that coproporphyrin I or III is excreted in association with pellagra.

Procedure.—The urine of all the in-patients in the medical department of the Miraj Medical Centre was examined for porphyrin content. Detailed clinical examination of these patients was done to detect the presence of one or more symptoms constituting the pre-pellagrous state. Urine specimens from some of the medical students were also examined for porphyrin, to serve as controls. Those patients who showed porphyrinuria were administered yeast and nicotinic acid, and the porphyrin determination in urine was repeated at regular intervals of a week or ten days, until porphyrinuria disappeared or persisted in spite of yeast and nicotinic acid therapy. One and a half drachms of yeast and 6 to 9 grains of nicotinic acid were given by mouth in these cases daily. In cases

(Continued from previous page)

When operation for chronic lacunar sepsis is refused or contra-indicated, I have found the almost daily application of equal parts of glycerine of carbolic, tincture of iron perchloride, and glycerine for some weeks if necessary, a useful method of diminishing size and improving drainage. The application should be pressed into the tonsils on cotton swabs. This does not cause that oedema of the mucous membrane which may follow the similar prolonged use of Mandl's paint, a reaction probably due to the iodine contained in this very popular and useful preparation.

of severe porphyrinuria, nicotinic acid was also given by injection. The possibility of a pathological porphyrinuria of an entirely different origin was not lost sight of and hence only these cases whose porphyrinuria disappeared by nicotinic acid therapy were regarded as of pellagrous origin.

The technique employed in all cases was more or less the same as that described by Beckh, Ellinger and Spies. Ten c.cm. of urine is placed in a separating funnel and is acidified with 0.2 c.cm. of glacial acetic acid to produce a pH of 4.0. Twenty c.cm. of ether is added and the mixture is well shaken to extract the porphyrin completely. The lower aqueous layer is removed from the funnel and the ethereal extract is washed with 15 c.cm. of distilled water. Three c.cm. of 25 per cent hydrochloric acid is then added. The mixture is again shaken and transferred to a test-tube in which the acid and ether layers are allowed to separate. The hydrochloric acid is examined for porphyrin. No attempt at quantitative estimation was made since this was not needed for the present inquiry. However, results were expressed in five grades negative (-), doubtful (\pm), slightly positive (+), moderately positive (++) and strongly positive (+++) depending on the gradation of colour.

The urine of 12 medical students (to serve as controls) was also tested for porphyrin but gave negative results.

Summary and conclusion

(1) Eighty-two specimens of urine from the medical in-patients of Miraj Medical Centre were tested for porphyrin content.

(2) Fifty cases out of the total of 82 showed the presence of porphyrin, thus giving a percentage of 61.

(3) Thirty-four out of the 50 cases of porphyrinuria showed one or more symptoms of pre-pellagrous state.

(4) Forty-five out of 50 cases of porphyrinuria received yeast and nicotinic acid in adequate doses, after which decrease or absence of porphyrin excretion was demonstrated in 39 cases, indicating that the porphyrinuria was evidence of pre-pellagrous state. Six patients did not show any decrease of porphyrin excretion in spite of nicotinic acid therapy. In the remaining five cases the effect of nicotinic acid and yeast could not be tried.

(5) Urine specimens from 12 apparently healthy medical students failed to show the presence of porphyrin.

(6) High porphyrinuria was noticed mostly in cases of chronic enteritis and colitis, of atrophic cirrhosis of liver. The latter observation may throw light on the incidence and aetiology of cirrhosis of liver.

NOTES ON COMMON SKIN DISEASES

IV. LEUCODERMA

By D. PANJA, M.B. (Cal.)

(From the Medical Mycology Enquiry under the Indian Research Fund Association in the School of Tropical Medicine, Calcutta)

LEUCODERMA is an acquired loss of pigment in the skin which manifests itself by the occurrence of ivory-white patches usually surrounded by normal or increased pigmentation. It is neither contagious, infectious, nor hereditary though at times there seems to be a familial tendency.

The race, age and sex have no relation with occurrence of the disease. The exact cause of leucoderma is not yet known; but it was found that there is evidence of intestinal derangement and the majority of the cases carry some infection in the intestine, protozoal, bacterial, or helminthic.

Apart from depigmentation the affected skin is not changed in any way; the activity of the sweat and sebaceous glands is not influenced, but the included hair shafts sometimes lose their pigment and become whitish or yellowish in colour; this condition of white hair is known as leucotrichia.

The patches are of various sizes and shapes, and can be classified into several types, e.g., the muco-cutaneous type affecting the lips, eyelids and external genitals; the pressure type affecting the waist as a result of the continuous pressure of the *dhoti*, *sari* or belt; the symmetrical type affecting both sides symmetrically; and the generalized type, where the white patches fuse to form large lobulated areas and even progress so far that the original complexion is obscured.

The lesions give rise to no subjective symptoms, but the whitened patches are hypersensitive to heat and light and tend to become inflamed readily when exposed to the sun. General health in leucoderma is not affected, though in sensitive persons considerable mental distress may be provoked. The affection may remain stationary for years and is generally slowly progressive in its course; in exceptional instances the patches disappear spontaneously.

The diagnosis of leucoderma is easy but it should be differentiated from partial albinism, pityriasis versicolor, leprosy, morphæ, atrophic macular syphilide, dermal leishmaniasis, melanoleucoderma, and lupus erythematosus.

1. In *partial albinism* the lesions are congenital and there is no characteristic bordering of the depigmented patch by hyper-pigmented skin. In *partial albinism*, the patient has always a blue iris.

2. *Pityriasis versicolor* might lead to confusion but its identity is easily established by the absence of ivory-white depigmentation and the presence of slight scaling in the lesions, and also by the microscopic finding of the fungus in the scales.

3. There will be no difficulty in differentiating leucoderma from anaesthetic *leprosy*, where the skin is lighter in colour and there are definite sensory changes that are not found in leucoderma.

4. In *morphe* the skin shows different grades of depigmentation with smooth, shiny, atrophic patches adherent to the underlying tissue.

5. *Atrophic macular syphilide* is a condition where multiple small atrophic areas are found on the trunk and extremities, and the atrophy is more marked than the depigmentation.

6. *Dermal leishmaniasis*, in its earlier stage, simulates leucoderma. But the lesions are not ivory-white, and, on the face round about the mouth, definite signs of granuloma are present. As a rule there is also a history of kala-azar or typhoid-like fever.

7. *Melano-leucoderma* generally affects the palms of the hands and the soles of the feet, and rarely the lips; it manifests itself by the appearance of patchy leucoderma and melanoderma (hyper-pigmentation) side by side, and also hyper-keratosis with desquamation. The hyper-pigmentation is more marked along the margins and sometimes extends higher up to the hands and feet. The disease is probably a late manifestation of syphilis, the serum reactions for syphilis are positive in all cases, and it responds to anti-syphilitic treatment.

8. The leucoderma-like depigmentation which is present in *lupus erythematosus* is due to cicatricial fibrous atrophy of the skin. Apart from depigmentation, the lupus patches are covered by the characteristic fine adherent horny plugs which, when removed, reveal enlarged follicular orifices. Moreover, the borders of the patches are markedly raised and infiltrated. These signs are absent in leucoderma.

Treatment.—The remark that 'no treatment has the slightest effect on leucoderma' in the textbooks of dermatology is not correct, as we have seen many cases responding with the following treatment:—

General treatment.—1. Careful investigation of the bowels by examining fresh stools for evidence of any intestinal infection.

(a) In the case of amœbic infection the treatment should first be directed towards the cure of this condition.

(b) If any bacillary (non-lactose-fermenter) infection is discovered, it should be treated by suitable autogenous vaccines, intestinal antisepsics and bacteriophage therapy.

(c) In the case of helminthic infection, the treatment should be given according to the nature of the infection.

2. There is nearly always evidence of irregularity of the bowels in leucoderma cases, so intestinal antisepsics should be given as 'a routine and liquor hydrargyri perchloridi (B.P.) in half to one drachm doses, twice daily after meals, is given for three to four weeks and is repeated after an interval of one to two weeks. The treatment is to be continued for three to six months or longer. Other intestinal antisepsics may also be tried.

3. *Diet.*—(a) Avoid highly spiced and stale food which may cause intestinal fermentation.

(b) Take germinating gram, beans and peas which are rich in vegetable protein and yield a good supply of tyrosin, a precursor of melanin.

4. Avoid pressure of the clothing on the site of leucoderma.

5. A change of climate is sometimes useful.

Local treatment.—1. Rub gently the oil of *bouchi* (*Psoralea corylifolia*) on the lesion twice a day for 5 to 10 minutes each time in order to cause a local stimulation of the melanoblasts.

The pigment begins to appear after a time, showing tiny spots on the margin of the patch or at the regions of the hair follicles.

Certain practical difficulties in the use of the bouchi oil.—(1) Sometimes the oil produces intense redness, burning and even vesication after a few applications and in susceptible persons the reaction may appear after a single application. In such cases the local application should be stopped at once and a soothing lotion, such as calamine lotion, should be applied on the patches several times every day until the redness and vesication subside. When the skin is normal, apply the oil again but diluted with olive oil, either 1 in 2 or 1 in 3 according to tolerance of the skin. In susceptible persons it is sometimes impossible to use the oil at all even in higher dilutions.

(2) In young children the diluted oil should be applied from the beginning.

(3) To certain tender parts, such as the muco-cutaneous junction of the lips, eyelids and external genitals, the diluted oil should be used.

2. Many years of experience of treating hundreds of cases at the Calcutta School of Tropical Medicine has led us to place our faith in external application of *bouchi* oil together with internal administration of intestinal anti-septics, but although persistence in this form of treatment is occasionally rewarded with success, partial or total failure has more often been the final result.

Recently, we have carried out a number of experimental treatments in which the oil, sterilized in an autoclave, has been injected intradermally instead of being rubbed on the skin.

Method of treatment.—The patch to be injected is carefully cleaned with alcohol, and the oil is injected intradermally with an ordinary hypodermic syringe fitted with a fine needle. The amount of oil in each injection is a single drop (between 0.05 and 0.1 c.c.m.). The number of injections varies with the size of the depigmented patch, small spots of 1 cm. or so in diameter only need a single injection in the centre. In larger patches the injections are spaced about 1 cm. or a little more apart, until the whole area is covered. In two to three weeks, formation of pigment can be noticed, beginning at the site of the needle puncture from which point it spreads centrifugally. If when deposition of pigment ceases, the contiguous areas of new pigmentation have failed to coalesce, a second, and if necessary, a third, course of injections can be given in the intermediate white patches, until the whole area is normally pigmented once more. If the patch to be treated is several inches in diameter, and in consequence needs numerous injections to cover it completely, it has been found better to give a few injections fairly wide apart in the first instance and to follow with intermediate injections a few days later, than to try to cover the whole area at one sitting. The reasons for this modification

ON THE IMPORTANCE OF MALNUTRITION IN THE AETIOLOGY OF THE ANÆMIC STATE IN TEA GARDEN COOLIES*

By K. P. HARE, M.B., B.S., L.M.S.S.A.
Hoogrijan, Assam

Object and scope of the investigation

THERE is reason to believe that malnutrition plays an important part in the causation of the anæmic state which is so universal in the coolie population of the tea gardens of Assam. It is certain that this anæmic state is apparent among children of tender years and certain work has indicated that it may even be congenital. An investigation into the relationships between the effects of nutrition in children and haemoglobin levels is, therefore, perfectly logical. Such dietary surveys as have been carried out among similar populations have shown that the chief defects in the dietary of the tea garden coolie are of animal protein, calcium and vitamins. The present investigation was designed to attempt an assessment of the relative importance of these three defects from the point of view of haemoglobin level.

For this purpose a list was made of all births which had occurred on one estate during the years 1929 to 1934, inclusive, and enquiries were made as to what had happened to each of the children. It was found that 111 children (51 boys and 60 girls) born during those years were still alive and resident on the estate. These children were interviewed in batches and the following particulars recorded:—Age, height, weight, hip-width, arm-girth (with the forearm flexed and extended), chest-depth (in inspiration and expiration), the existence of stigmata of hypovitaminosis, and the amount of haemoglobin in grammes per 100 c.c.m. of blood. For the last, the Sahli haemoglobinometer was used. In each case, from the arm, chest and hip measurements, the ACH index was calculated and compared with the standard as modified by Aykroyd to suit small hip measurements.

* Based on a note read at the 1941 Assam Provincial Medical Research Conference.

(Continued from previous column)

are that injections are followed by a good deal of pain, and if many are given at one time the pain is very severe, and also injection of the oil is sometimes followed by a small focal ulcer which remains small if the injections are wide apart; but, if several of these ulcers were to occur in adjoining injection sites, they might coalesce and form a relatively large lesion. It should be noted, that apart from the extra discomfort at the time and the subsequent scarring, ulceration has no ill effects on the final result as the scar always becomes pigmented.

General observations

Though a very large proportion of the children were obviously under-nourished, only six were 'selected' by the ACH system, a percentage of 5.4. This unreliability of the system for use in India without further modification has been commented on by other workers and is presumably due to malnutrition affecting muscular and skeletal development fairly equally so that all measurements are small.

The number of children showing stigmata of hypovitaminosis together with the mean haemoglobin level of each category will be found in table I. In this instance, age groups have been ignored because it will be apparent from later tables that there was little correlation between haemoglobin and age and, in fact, only two age groups among the girls and one among the boys had mean haemoglobin values higher than the mean haemoglobin value of the children without stigmata. There was a slight but definite deficit of haemoglobin in those children who showed evidence of present hypovitaminosis but this was not the case in those whose previous lack of these substances had been righted.

TABLE I
Correlation between stigmata of hypovitaminosis and haemoglobin level

Category	Number in category	Mean haemoglobin value in category
No stigmata	59	7.20 g. per 100 c.c.
Healed xerophthalmia only	3	7.60 do.
Phrynodermia only	11	6.99 do.
Xerophthalmin only	29	6.96 do.
Phrynodermia and xerophthalmia.	9	6.98 do.

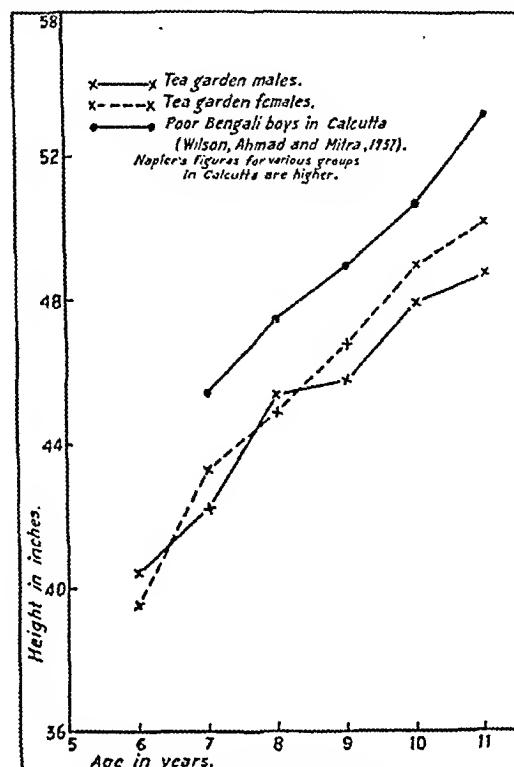

The height-for-age and weight-for-age were both lower than in any series I have seen recorded for India. Details are recorded in graphs 1 and 2.

Details for the hip-width-for-age are rerecorded in graph 3. It will be seen that a very exact correlation existed between these two variables.

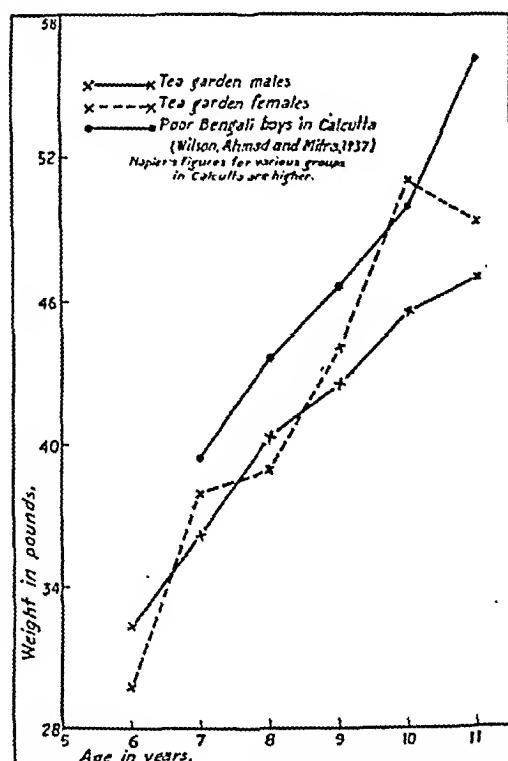

Graph 4 illustrates in graphical manner the mean haemoglobin content of the blood of boys and girls in this series according to the year of birth. It will be seen that there is only slight correlation between age and haemoglobin content in marked contra-distinction to that noticed in the other three graphs. I am unable to offer any explanation of this fact. One interesting fact emerges. The haemoglobin content of the blood of the average healthy adult tea-garden coolie has been previously shown to be slightly lower than three-quarters of that of healthy Calcutta adults. In this series content is slightly less than three-quarters of Calcutta children of the same age examined by Napier and Das Gupta (1940).

Correlation of measurements with haemoglobin content

In tables II to VI are recorded the mean haemoglobin contents for both sexes in each age

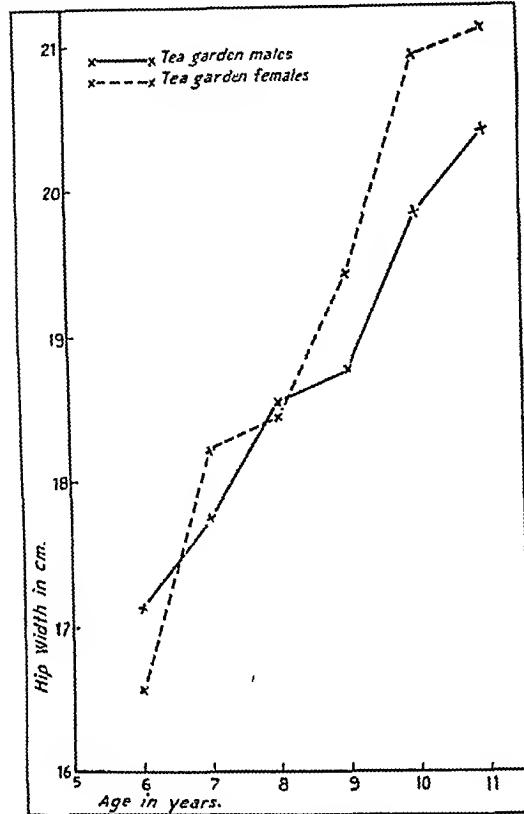

Graph 1.—Height-for-age.

Graph 2.—Weight-for-age.

group of those whose measurements are below and above the average for the group. The only measurements which demonstrated any degree

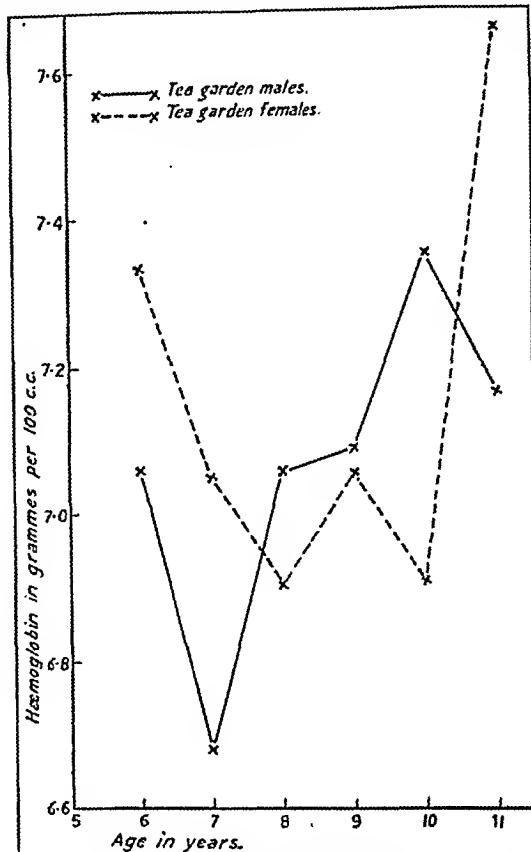

of correlation with haemoglobin (and in both cases the correlation was poor) were height and arm-girth. The latter finding suggested that muscular development, which is presumably dependent on animal protein intake, might be investigated more closely.

Graph 3.—Hip-width-for-age.

Now it had been noticed during the course of the investigation that the chest-depth was not a highly variable factor in these children. Given this fact, it is obvious that the size of the ACH index in children with similar hip-widths will vary directly with the arm-girth. If then, haemoglobin production is most largely dependent on animal protein intake, in any group of

children with the same hip-width, those with the greater arm-girth should be more richly

Graph 4.—Hæmoglobin for age.

Note.—The average values for both sexes are slightly lower than 3/5 of those for corresponding age groups in Calcutta as determined by Napier.

endowed with haemoglobin than those whose arms are smaller. A reclassification of the children on these lines resulted in the figures quoted in table VII. There is certainly a greater degree of correlation between the size of the ACH index and haemoglobin content than was seen in any of the other tables but I do not consider it sufficient to be convincing.

Conclusions

It is probable that various vitamins, animal protein and calcium are, in the sense of defective intake, all important in the aetiology of the anaemic state of the tea garden coolie. The present investigation has failed to indicate any one as being of special importance but has suggested that their relative importance may be in the order vitamins, protein and calcium.

THE BENZIDINE REACTION OF BLOOD SIMULATED BY A CLAY (BENTONITE)

By S. D. S. GREVAL
LIEUTENANT-COLONEL, I.M.S.

Imperial Serologist and Chemical Examiner to the Government of India

and

A. B. ROY CHOWDHURY, M.B.
Third Assistant

(From the Imperial Serologist's Laboratory, School of Tropical Medicine, Calcutta)

THE intention is to draw attention to a reaction with benzidine (para-diamino-diphenol) given by a clay known as bentonite.

The benzidine test detects blood in traces, a dilution of 1 in 300,000. It is best performed thus: to a small cutting or scraping of the stain placed on a white dish are added a drop of a saturated solution of benzidine in glacial acetic acid and a drop of 3 per cent hydrogen peroxide; a brilliant blue coloration develops immediately (Lloyd, 1935). The basis of the reaction is the oxidation of the benzidine by oxygen liberated from the peroxide by a peroxidase present in haemoglobin or its derivatives.

That fruits and vegetable juices, particularly the potato juice, also provide the oxidase for the oxidation of the benzidine is known. That the plant juice contains auto-oxidizable substances of a phenolic nature which are capable of combining directly with atmospheric oxygen to form organic peroxides from which oxygen is readily transferred to an oxidizable substance by a peroxidase present in the same juice, is also known (Parsons, 1933).

The clay bentonite has also been found to react with benzidine. It reacts like the plant juice containing the auto-oxidizable substances and also like the potato juice. The scrapings from its exposed surface turn the benzidine greenish blue, even in the absence of hydrogen peroxide. The same scrapings after the removal of (loosely bound?) oxygen, by submersion in an excess of physiological saline overnight, cease to affect the benzidine in the absence of the peroxide: the coloration now develops only on the addition of the latter reagent. The scrapings after they have been dried and exposed to air react without hydrogen peroxide again.

The clay does not give the reaction of thallium with benzidine.

The initial chemical reaction of the clay, although slower than that of blood, creates a presumption in favour of presence of blood. The presumption is not disposed of until a negative spectroscopic test is obtained. This simulation of the reaction of blood by an inorganic substance, even at only one step of the routine, is recorded in the interest of forensic chemistry.

The writers are indebted to the Geological Survey of India, Calcutta, for the identification and the following brief description of the clay:—

"Bentonites are clays that have the clay mineral "montmorillonite" with the chemical composition of $(\text{MgCa})_2\text{Al}_2\text{O}_5 \cdot 5 \text{SiO}_4\text{H}_2\text{O}$, for their chief constituents. These clays are of very small grain size and absorb large quantities of water, swelling enormously in the process, and they have the property of remaining in suspension in their water dispersions."

The swelling property is reversible; the clay can be dried and re-swelled an infinite number of times; this activity remaining unaffected by temperatures below 450°F. It can be readily distinguished from other clays by its reaction with benzidine.

Uses.—Bentonites are used in metal foundries as a bonding material for moulding sands, in drilling muds, as a detergent in the laundry, as a plasticizing agent in ceramic materials, as a standard suspending, spreading and adhesive agent in horticultural sprays and

STUDIES ON *LEPTOSPIRA ICTERO-HÆMORRHAGIÆ* IN RATS IN BOMBAY CITY

By M. N. LAHIRI

(From Haffkine Institute, Bombay)

ACCORDING to Ido, Hoki, Ito and Wani (1916 and 1917) it was Miyajima who first drew attention to the finding of spirochaetes resembling *Leptospira icterohaemorrhagiae* in the kidneys of the field mouse. The discoverer subsequently reproduced the disease in the guinea-pig by inoculation of the infected kidney of the field mouse. These workers, acting on this suggestion, examined a number of wild rats. The presence of similar spirochaetes were detected in the kidney or urine of the rats and were also demonstrated by means of guinea-pig inoculations. Since then, investigations have been carried out in different parts of the world by different workers. High prevalence of infection among rats has been observed both in places where human cases have been known to have occurred and in places where the disease in man is unknown. Langworthy and Moore (1927), for instance, detected a high incidence of the infection among rats in the New York State, 40 per cent by direct examination and 60 per cent by serological tests, and yet as far as is known no human cases have been reported from that area.

(Continued from previous column)

insecticides, in clarifying turbid waters and purifying sewage, in gelatinizing wet-mash poultry foods, for clarifying wines, in cosmetics, and pharmaceuticals.'

The original specimen of the clay which was found to react with benzidine was an exhibit designated 'stone' in a murder case. Other specimens resembling it in appearance, consistency and reaction were obtained from the aforesaid department. It was a compact lump of a bluish-white substance which could be easily scraped and ground.

The use of the clay in cosmetics is worthy of note. A brand of talcum powder was found to react with benzidine. It is also noted that the reaction between benzidine and bentonite is known to geologists.

An acknowledgment

The writers are indebted to V. P. Sondhi, Esq., M.B.E., M.Sc., F.G.S., of the Geological Survey of India, Calcutta, for the aid received.

(Concluded at foot of next column)

Anderson and Wagle (1933) first pointed out the existence of infection in rats in the city of Bombay. The present investigation was undertaken to carry out a systematic examination of rats not only to demonstrate the infection but also to isolate and identify the strains with particular reference to their serological classification. Because, if the murine strains and human strains when obtainable are serologically identical, it might throw some light on the possibility of the rat playing a part in the transmission of the disease. For this purpose, rats from a particularly congested area of this city were trapped and brought alive to the laboratory. In all a series of 125 rats was examined.

Methods

1. *Direct examination*.—It has been shown by several workers that the leptospiræ in rats are confined to the convoluted tubules of the renal cortex where they are discretely localized. Therefore, major portions of the cortex of both the kidneys from each animal were emulsified in sterile normal saline and care was taken to break up the tissues thoroughly. The emulsion thus prepared was examined by dark-ground illumination. Three preparations were examined before returning a sample as negative.

2. *Animal inoculation*.—As a measure of economy it became necessary to pool the kidney emulsions of three or four rats in which leptospiræ could not be detected by dark-ground illumination. Three c.cm. from each of the mixtures thus made were inoculated intraperitoneally into a young guinea-pig, whereas in those emulsions showing leptospiræ a separate guinea-pig was used in each case for the infective material. The peritoneal fluids of the guinea-pigs were aspirated and examined on the 4th, 6th and 7th day after inoculation for the presence of leptospiræ. As a rule, the animals were kept under observation until six weeks after inoculation.

3. *Culture of the kidney cortex*.—Small pieces of the tissue were inoculated into Vervoot's medium and incubated at room temperature (21° to $29^{\circ}\text{C}.$). The cultures were examined regularly at intervals from the 8th day onwards to the end of three weeks after inoculation.

4. *Serological testing of the rat's serum*.—As soon as the rat was killed by means of chloroform the chest wall was opened aseptically and blood was collected from the heart with a fine capillary pipette. The rat's blood in general clots very quickly after death. The sera of rats were tested for the presence of agglutinins and lysins against a classical strain of *L. icterohaemorrhagiae* kindly supplied by Dr. B. M. Das Gupta of the School of Tropical Medicine, Calcutta. Varying dilutions of each serum ranging from 1 in 10 to 1 in 80 were first made. An equal volume of rich young live culture in Vervoot's medium was added to each of the dilutions of the serum. The final dilutions of the serum, therefore, were 1 in 20 to 1 in 160. As a control, rabbit or normal human sera in dilution of 1 in 10 was used. The tubes were incubated at $37^{\circ}\text{C}.$ for $2\frac{1}{2}$ hours and at the end of this period samples from each tube beginning from the highest dilution of serum were examined by dark-ground illumination. Further dilutions were not necessary except in only one instance when dilutions up to 1 in 640 had to be made.

Observations

1. The leptospiræ were demonstrated in only eleven specimens of the kidney emulsions examined by dark-ground illumination. Incidental to the search for leptospiræ in these animals it will be of interest to record that *Trypanosoma lewisi* were seen in the blood of five rats.

2. Forty guinea-pigs were inoculated with the kidney emulsions. These animals may be arranged in the following groups:—

(a) Ten guinea-pigs were injected with infective material positive by the above method. One specimen, although it showed leptospiræ, could not be inoculated as guinea-pigs were not available. Of these ten, four failed to show any evidence of leptospiral infection and remained alive and well during the observation period. Four animals succumbed to the infection with typical signs, from the culture of the heart's blood of three animals, strains of leptospira were obtained. With regard to one the animal died late in the night hence its liver emulsion showing numerous leptospiræ was inoculated into a second animal for the isolation of the strain which, however, did not show any evidence of infection. A month later, far beyond the usual fatal period, this animal received a massive inoculation with heavily infected guinea-pig liver, but it remained insusceptible to infection. In the remaining two animals, although they died within the usual fatal period, there was no jaundice, and characteristic lung haemorrhages as well as haemorrhages in the groin were the visible signs of infection. No leptospiræ were seen either in the body fluids or in any organs. Buchanan (1927) also recorded similar findings in his studies.

(b) Of the remaining thirty animals which received the pooled emulsion only two died of infection and at autopsy exhibited the complete picture of the disease. The heart's blood collected almost immediately after death was cultured and thus two strains of leptospira were obtained. This brings out an important fact that, if only very few leptospiræ are present in the kidneys, an infected rat may escape detection by the direct method but infection can be demonstrated by animal inoculation.

3. Kidney substance of seventy-eight rats was cultured. In all twenty-seven were free from bacteria of which only two gave a pure growth of leptospira. The positive cultures obtained were, however, from rats which showed leptospiræ in their kidneys. The rest showed bacterial growth and in several instances a motile organism was isolated which on culture was identified as *Bact. pseudo-asiaticum*. Evidently, the rats had this bacterial infection. Das Gupta (1940) also reported similar heavy infections with salmonella-group organisms among rats in Calcutta.

4. Sixty-eight samples of sera were examined of which only six gave positive reaction. Four samples reacted in a dilution of 1 in 20 and one in a dilution of 1 in 80. The sixth sample agglutinated up to a titre of 1 in 640. Of these six positive specimens four were collected from the animals in whose kidneys leptospiræ were seen. It is difficult to draw any conclusion from such a low titre. It may be coagglutinins or that the serological properties in rats may persist only for short periods. With titre of 1 in 80 it

is possible that the rat was infected with the classical strain whilst the titre of 1 in 640 is definitely suggestive of infection.

The five strains of rat leptospira recorded above, all reacted up to the full titre with anti-leptospiral serum (classical).

Comment

From the above studies it is evident that the dark-ground method of examination yields the best results for the demonstration of infection. But for the purpose of isolation of the organism either the kidney cortex must be cultured or an emulsion of the ground-up kidney tissues inoculated into a guinea-pig. As regards culture, although a large number of positive results have been recorded by many observers, in my experience the results were far from satisfactory. This was in most instances due to the simultaneous infection by *Bact. pseudo-asiaticum* in rats, already referred to.

With regard to the animal inoculation, it may be mentioned that the method has obvious advantages. Even infected rats which may escape detection by the direct method when scanty leptospiræ are present often show infection by this method. But the drawback is that in certain guinea-pigs the disease could not be reproduced. It may be either due to variations in virulence of the organism or due to individual resistance towards susceptibility to infection. Observation recorded under animal inoculation lends strong support to the later contention. Several workers by means of serological tests have demonstrated infection in rats and some investigators reported the titre to be very high. It is shown, however, that in the series most of the infected rats reacted in a very low titre, whereas positive reactions were obtained in two rats not carrying leptospiræ. These observations, therefore, confirm the findings of Zimmermann (1930). Thus, the importance of the combination of various methods is stressed.

Summary

The kidney cortex of one hundred and twenty-five rats trapped in one congested area of the city were examined by dark-ground illumination and by animal inoculations. Seventy-eight specimens of kidney tissues were cultured in Vervoort's medium. Sixty-eight samples of sera were tested for the presence of agglutinins and lysins.

Leptospiræ were detected in the kidneys of eleven rats by direct method and of only two by animal inoculations. Two other animals showed evidence of infection serologically. The rats found to be infected by the above methods were all of the species *Rattus norvegicus* except one which was of the species *Rattus rattus* and whose serum was found to contain anti-leptospira agglutinins with a titre of 1 in 640. The five strains of rat leptospira isolated all belong to the classical group.

OBSERVATIONS ON THE RELATIONSHIP BETWEEN MALARIA AND PISTIA IN TWO VILLAGES IN MURSHIDABAD DISTRICT

By D. N. ROY, M.D., D.T.M.

Professor of Medical Entomology, School of Tropical Medicine, Calcutta

and

P. C. ROY, M.B., D.P.H.

District Health Officer, Murshidabad

ONE of the writers (P. C. R.) during the course of his duties as health officer of Murshidabad district has made extensive observations since 1928 on the epidemiology of malaria in relation to the presence of pistia and finally applied the results to practical tests in several isolated highly endemic localities in the district. From the success obtained by systematically removing pistia from the breeding places, he concluded that malaria and pistia were interrelated at least in the district of Murshidabad.

He suggested that mosquitoes bred out from larvæ which have opportunities to feed on pistia become susceptible to plasmodial infection. According to him, excepting *Anopheles subpictus* and *A. vagus*, any and every anopheline mosquito breeding in association with pistia is dangerous to the community. It should, however, be recalled that it is not known whether larvæ really feed on pistia.

Laboratory experiments, on the other hand, conducted by one of the writers (D. N. R.) with *A. stephensi*, showed no difference whatever in the comparative infectivity in two samples, one bred out with pistia and the other without it. In these experiments larvæ were collected in nature and were not reared from eggs.

It is known that mosquito larvæ are dependent for their breeding chiefly on the ecological conditions of the water which are set up by

plants and animals. The association of these two factors plays an important rôle in the development and sustenance of flora and fauna of a water reservoir and the parts played by them are interdependent.

It was therefore the object of our research to determine the part played by this particular plant *Pistia stratiotes*, in the reduction of the local malaria-carrying anopheles.

As there was no information available on the particular species responsible for malaria in that locality, it was necessary to approach the subject from another direction by noting the improvement brought about mainly in the spleen indices, mortality rates, etc., by anti-pistia measures.

The local operations were conducted by the junior writer at the advice of the senior.

Two villages, Khosbaspur and Ranagram, were selected for this study. In Khosbaspur pistia which was usually present in abundance in many tanks was removed and, except pistia, as far as possible other types of vegetation were not disturbed. When removal of pistia caused denudation of nearly all vegetation, other plants mainly salvinia and hyacinth were introduced. In a neighbouring village, Ranagram, situated at a distance of two furlongs from Khosbaspur, pistia was alone allowed to remain while other weeds

such comparative data have been shown in table II. In a population undergoing quininization the spleen and average spleen rates are more markedly affected than the average enlarged

July 1939 ..	1.905	0.054	4.650	2.0	No corrections for height have been made.
December 1940 ..	0.520	0.948	3.250	4.181	

were eliminated. Except for pistia, the conditions in the two villages were more or less identical.

Tanks and ricefields were potential sources of anophelines in the two localities.

The population in Khosbaspur and Ranagram were 1,116 and 592 during the experimental period and the areas covered by them were 774 and 677 acres respectively.

The observations were carried out from July 1939 to December 1940, and as the malaria incidence generally attains its peak in November and declines in June, this period included two malaria seasons.

The difference in the spleen rate of these two villages, Khosbaspur and Ranagram, from 1939 to 1940, i.e., before and after anti-pistia measures were undertaken, are shown in table I.

As improvement brought about by any anti-malaria measure can be better judged from 'average spleen' and 'average enlarged spleen',

sary at Gokarna. Lest this factor might interfere with the results, even the normal annual quinine supply to this Union Board was stopped.

January-June. July-December.	15 8	10 5	23 15
January-June. July-December.	7 22	11 12	29 23

An examination of the data presented above clearly reveals that in Khosbaspur there was a marked improvement in the health of the population after pistia was removed, whereas a deterioration was noticed in the other village where pistia was allowed to grow freely. We will now adduce evidence in support of the fact that pistia had a direct bearing on the fluctuation of malaria in the two localities.

(1) The increase of malaria in other places in the district, especially in the neighbouring villages, during the same period.

(2) Its decline in autumn in a pistia-free area when a rise is the rule.

The spleen indices of a few neighbouring villages tabled below reflects the condition of health as regards the incidence of malaria in the rest of the district and it can be stated that 1940 was a particularly bad year for malaria. Under these circumstances the reduction of malaria in pistia-free places must be directly associated with the particular operations undertaken in the locality.

TABLE VII

Places	Distance from Khosbaspur	SPLEEN RATE	
		1938 December	1940 December
Gobarhati ..	3 miles	40	80
Patanda ..	3 miles	60	100
Mahalandi ..	3 miles	50	70
Gokarna ..	1/2 a mile	10	46

During autumn, the epidemic season, there is always a tendency for the spleen rate to rise. When such variation of the spleen rates in the two experimental villages given in table VIII is compared, it is noticed that while an autumnal rise is recorded in the one, there is a gradual decline of the spleen rate in the other. This suggests that the local operations are directly responsible for preventing the spleen rate from rising in autumn in the pistia-free village.

TABLE VIII
Seasonal and non-seasonal variations of the spleen rate and average spleen

Time of the year	SPLEEN RATE, CM.		AVERAGE SPLEEN, CM.	
	Khosbaspur	Ranagram	Khosbaspur	Ranagram
June 1939 ..	41.0	2.7	1.905	0.054
December 1939 ..	34.8	10.0	1.25	0.314
June 1940 ..	21.7	9.0	0.851	0.337
December 1940 ..	16.0	22.6	0.52	0.948

Whether the rapid reduction of the spleen rate in the experimental villages from 41 in July 1938 to 16 in December 1940, would or would not have resulted, if the flora in the different breeding places were not interfered with, may now be discussed. The spleen rates of two villages, Khosbaspur and Laharpura, collected by Sinha (1940) may throw some light on this point. He carried out similar anti-pistia experiments and these two localities in the same district were used by him as controls.

Showing the natural fluctuation of spleen rates as compiled by Sinha.

Time of the year	Khosbaspur	Laharpura	REMARKS
July 1933 ..	1.4	24.1	
November 1933 ..	7.2	24.3	
June 1934 ..	3.4	22.9	
November 1934 ..	10.1	8.3	Flood, 1934.
July 1935 ..	8.8	5.4	Drought, 1935.
November 1935 ..	0.7	0.0	
July 1936 ..	1.6	1.6	Drought, 1936.
January 1937 ..	2.1	2.5	
June 1937 ..	2.1	0.0	
October 1937 ..	3.0	0.0	
January 1938 ..	16.3	0.0	
June 1938 ..	4.7	0.0	
December 1938 ..	54.5	7.0	

The above findings indicate that under certain circumstances the spleen rate may normally fluctuate within narrow limits. But due consideration should be paid to the operation of such abnormal conditions (flood and severe drought, during 1934, 1935 and 1936), on the epidemiology of the disease. In contrast to the usually small degree of fluctuation noticed under normal conditions, the decline of the spleen rate resulting from anti-pistia measures is marked and rapid. This is also very well exemplified by the following records compiled by Sinha in a neighbouring hyperendemic locality during the period anti-pistia operations were in existence.

The nature of the decline of spleen rate in Munigram in course of anti-pistia operations (Sinha)

Time of the year	Spleen rate	REMARKS
July 1933 ..	87.5	Before removal of pistia.
November 1933 ..	83.3	After removal of pistia.
November 1934 ..	63.2	
November 1935 ..	26.5	
October 1937 ..	6.6	
December 1938 ..	1.7	

The rise of the spleen rate in the one and its corresponding decline in the other cannot therefore be correlated with any other factor except pistia. It seems illogical to select two places so near to each other for the demonstration of the effect of pistia on malaria knowing that normally mosquitoes can fly a longer distance than two furlongs. However, the observations recorded by Sweet and Rao (1934) in connection with malaria control in Mysore State may be equally applicable in our case. Although the control operations were confined to Bangalore City where a sharp drop of malaria was noticed, in the adjacent civil and military stations outside the control area there was evidence of an increase.

At the time this experiment was undertaken it was contemplated studying the comparative

difference in the numerical ratio of adult and larval anophelines in the two localities. Unforeseen circumstances interfered with this plan. Although it has not been possible to determine the local carrier species, a strong suspicion rests on *A. philippinensis*, even though Sinha recorded only one adult and we found none.

The success of an anti-malaria measure is universally judged by the improvement of the health of the population manifest in the reduction of the spleen rate, average spleen, more especially average enlarged spleen, etc. It must therefore be admitted that there is a strong case in favour of pistia. It is not, however, possible to answer at this stage whether the improvement that has been noticed following the removal of pistia is merely temporary, although the junior writer claims that he has to his credit other areas in the same district which have been kept almost free from malaria for a number of years by systematically removing pistia.

According to Sinha (1940) general weed removal is more responsible for the improvement than the removal of pistia alone. It has already been pointed out that in Khosbaspur other plants, e.g., hyacinth and salvynia, were introduced into tanks from where pistia was removed and in Ranagram pistia was allowed to grow more freely by eliminating other plants.

The coexistence of a particular type of vegetation and *A. philippinensis*, which is possibly the local vector, has been emphasized by Bose (1934). On the breeding habits of this mosquito in an adjacent district Bose remarked 'in two of the clean tanks at Birnagar, we attracted them by introducing certain kinds of vegetation and repelled them by removing the same vegetation' and 'even when tanks are re-excavated, *A. philippinensis* recommences to breed in them as soon as certain kinds of vegetation reappears'.

The association of a particular species of mosquito with pistia is very well known; a few examples may be cited to illustrate this. Mieldazis (1930) reported the coexistence of *A. philippinensis* and pistia in the Philippine Islands. Kariadi (1938) noted a definite correlation between *Mansonia uniformis* and Eichornia and between *M. annulifera* and pistia in the Netherlands East Indies. Both Leeson (1937) and Evans and Garnham (1936) recorded the intimate association between the breeding of *Anopheles rivulorum* var. *garnhamellus* and the existence of *Pistia stratiotes* in East Africa, South Rhodesia and Kenya. Rozeboom (1935) found *A. bachmanni* usually in patches of pistia. Although *Ficalbia minima* are free-living and do not depend on pistia for their supply of oxygen, they were never seen by Iyengar (1935) in the absence of this plant.

Summary

Epidemiological studies on the relationship between pistia and malaria have been carried

out in two villages in the district of Murshidabad (Bengal). In one of them pistia was removed from tanks which are the potential sources of anopheline mosquitoes and in its place other vegetation was introduced. In the other village all vegetation except pistia was removed. At the end of two malaria seasons a progressive and at the same time a marked decline of malaria was noticed in the former village and a corresponding increase in the other. The association of a particular type of vegetation with the breeding of *A. philippinensis* in a neighbouring district has previously been reported.

A Mirror of Hospital Practice

EYE COMPLICATIONS OF DERMAL LEISHMANIASIS

By L. EVERARD NAPIER, F.R.C.P. (Lond.)
E. O'G. KIRWAN, C.I.E., M.B., B.Ch., F.M.C.S.I.
LIEUTENANT-COLONEL, I.M.S.

and

G. SEN, M.B. (Cal.), D.T.M.

Mohi Uddin, male, aged 20 years, was admitted on 7th July, 1939, to the hospital attached to the Calcutta School of Tropical Medicine. He gave no history of kala-azar, but a vague history of some undiagnosed fever in childhood. Nodules began to appear on different parts of his body about five years ago.

Present condition.—He had a distinct reddish flush of his cheeks and chin, and at times, after exposure to the sun, his whole body showed this flush. He had typical post-kala-azar dermal-leishmaniasis nodules and depigmented areas all over his face and body. Those on his face, and especially those at the skin-mucous-membrane junctions, were smooth reddish bullous nodules, soft and rubbery to feel, but formed of solid though loose-textured tissue. The eyelids were involved in these swellings, his eyes were watery, and he kept them half closed (*vide plate XXXI, figures 2 and 3*); also, he had photophobia.

A nodule was removed from his chin; a smear made from the cut surface of this nodule showed abundant leishmania.

Both corneaæ showed numerous opacities; the right had a pannus all round the periphery, and the left was almost completely opaque from the nodular growth covering half of it. There was marked vascularization. The vision in the left eye was almost nil but improved to 'counting fingers at one metre'; in the right eye vision was only sufficient for him to walk alone with difficulty, but it improved to 3/60.

He was sent to the eye hospital on 20th September, 1939; at this time the eye condition was as follows:—

Both upper eyelids are somewhat thickened, but the lower eyelids are normal. The palpebral conjunctivæ are not involved, and the bulbar conjunctivæ are only affected in the vicinity of the limbi. The corneaæ show a diffuse haziness, multiple opacities, marked pannus extending all round the periphery, deep vascularization and infiltration into the substantia propria.

The most striking point is the presence of nodules in the vicinity of the limbi and these have spread superficially to form a pannus and deeply to form an interstitial keratitis. Vascularization is very marked, and as the disease has progressed it has gradually extended around the corneaæ. The sclera approximating the cornea is involved in part and the disease has probably originated from here as an episcleritis.

The ciliary body and iris are very slightly involved; there are some posterior synechiae but no evidence of active inflammation. There is no anaesthesia and very little pain. The left eye is more affected than the right eye.

The clinical picture might on first examination be confused with trachoma or leprosy, if it were not for the presence of typical post-kala-azar dermal-leishmaniasis nodules on the patient's face and body; but on closer observation the appearance is very different. Blepharospasm, photophobia and epiphora although present were not marked signs.

Treatment.—He was given potassium iodide, gr. xv, t.d.s.; the dose was gradually increased until by the 18th day he was taking gr. xxx, t.d.s., which dose he took for 14 days. On the 24th day of the iodide course he was given neostibosan 0.3 g. every other day up to 12 doses. After a further month's interval he was given urea stibamine, doses up to 0.2 g., on alternate days for 12 doses.

During the interval, one or two isolated nodules were injected with 2 per cent berberine sulphate. The injected nodules shrank slowly but did not disappear.

Progress.—After a month of potassium iodide, the patient felt very ill and his face was swollen. He improved immediately the iodide was discontinued. It was noticed that the lesions were slightly reduced.

After the second course of antimony the skin condition was distinctly better and he left hospital.

Re-admission.—He was re-admitted on 6th July, 1940; the nodules had by then nearly disappeared (*figure 4*), but his sight was still poor and he was anxious to have further treatment with the idea of improving this.

Figure 1, plate XXX, shows the condition of the eyes at this time.

He was again sent to the eye hospital with a request that the growth over his cornea should be removed for examination for the presence of leishmania.

The large diffuse nodule on the left eye was incised at the limbus and a small piece of the inflammatory tissue removed. Smears from this tissue showed the presence of leishmania.

PLATE XXX

Keratitis due to dermal leishmaniasis.

R. E.

L. E.

Fig. 1.

PLATE XXXI

Fig. 2.—Showing condition on first admission.

Fig. 4.—Showing condition at time of re-admission.

Fig. 3.—Showing condition on first admission.

Fig. 5.—Showing condition on final discharge.

Treatment.—He was given 20 injections of aminostiburea, 0.2 g. each, on alternate days from 7th August to 14th September, when he was discharged.

At the time of discharge his sight was much further improved (figure 5).

Sight.—On the 20th September, 1939, the vision was:—

R. E. 3/60: L. E. 1/60

After treatment on the 20th July, 1940, the vision was:—

R. E. 6/36: L. E. 2/60

Comment.—This was a fairly typical case of post-kala-azar dermal leishmaniasis; in Bengal, it has been calculated (Napier, 1931) that about 5 per cent of persons suffering from kala-azar eventually develop the local lesions. If the history is correct the patient recovered from the visceral infection without any specific treatment; this is not unusual, for about 25 per cent of patients with this condition give a similar history. The bullous lesions are not seen as frequently as the ordinary nodular lesions, which this patient also showed, but are not rare, and the photo-sensitive flush is quite common.

The only uncommon feature in this case was the condition of the eyes.

The reference in the literature to leishmanial infections of the eye appear to be rare. On the subject of leishmanial keratitis, Duke-Elder (1938) in his well-known textbook writes:—

'Corneal involvement by Leishmania is very rare. The mode of infection is not proven, but it is probably by direct inoculation from the fingers: it does not occur in persons who have had the disease, and the corneal infection confers subsequent general immunity. The clinical picture produced is characteristic (Chams, 1929). Starting with irritative symptoms of pain, photophobia and lacrimation, a superficial erosion or a phlyctenule-like efflorescence appears on the cornea, which is quickly associated with a deep infiltration. The infiltration pervades the entire cornea, in the centre of which an abscess forms, which in the 3rd or 4th week discharges itself either exteriorly or into the anterior chamber, the result being blindness, or loss of the eye. Treatment should be by the application of mild antiseptics, as methylene blue with atropine, combined with general arsenical treatment: cauterization involves the formation of unusually dense scars. If it is undertaken energetically before the end of the 2nd week the prognosis as regards the eye is good, while fair vision may be retained: if its inception is delayed until the 4th week more than half of the cases end in perforation.'

We have not consulted the Chams reference, but presumably he refers to *Leishmania tropica* infection, secondary to oriental sore. In this condition auto-inoculation is a recognized mode of spread of the infection. Oriental sore does not occur in Bengal and this patient never left the province. In this case the skin condition is due to an haematogenous infection of *Leishmania donovani*. In this form of dermal leishmaniasis the assumption is that the wide distribution of the leishmania takes place at the time of the visceral infection when the parasites are in the peripheral blood. Whilst the dermal lesions may not all reach the clinical threshold at the same moment, for some develop more slowly than others, they do not appear in successive crops, there is no evidence that extension

from the earlier lesions ever takes place, and the question of auto-inoculation need not be considered as the lesions are non-ulcerative. As the cornea is a non-vascular tissue, the leishmania cannot have been there from the time of the visceral infection and in this case extension from the sclera must have taken place, as occurs in tuberculous episcleritis.

The response of the dermal lesions to treatment was characteristically slow, but, as is usually the case, the condition was eventually cured, and in this instance the eye lesions also showed considerable improvement and possibly after a lapse of time these will have improved further, but we have now lost track of this patient.

Had this condition been left untreated, we do not anticipate that it would have followed the course described by Duke-Elder, for neither ulceration nor abscess formation occur in post-kala-azar dermal leishmaniasis (*L. donovani* infection), whereas the former is the rule in oriental sore (*L. tropica* infection); it is however probable that the infiltration and vascularization of the cornea would have proceeded further and eventually produced complete blindness.

AN INTERESTING CASE OF MALARIA

By S. N. MITRA

Medical Officer, Namdang Tea Estate, Margherita P. O., Upper Assam

In this district during the last 12 years' practice, I cannot recall more than two intractable cases of malaria that failed to respond to quinine, and so the following case can be described as rare even in a hyperendemic area of malaria.

A male, aged about 46 years, working as a factory Babu for the last 6 years. During this period he had suffered from malarial fever twice. During the monsoon he is very particular to take prophylactic quinine (gr. 5 in a capsule or as a pill) daily.

First attack.—On the 18th July, 1938, at about 11 a.m., I was called to attend him for fever, and I found him in the following condition:—

Temperature 99.8°F, rigor and headache present. Bowels moved once and not constipated. Spleen not palpable. Other signs and symptoms—nothing noteworthy. A blood film both thick and thin was taken, and showed no parasite (taking prophylactic quinine daily).

Treatment.—One calomel powder of gr. 3 to be followed by a dose of Epsom salts 2 hours later.

I instructed the patient to take the following mixtures:—

Mist. alkaline 1 oz. t.d.s.

Mist. quinine bihydrochloride (gr. 7 1 oz. to 1 oz.)

t.d.s. 1 hour after alkaline mixture.

At about 7 p.m. the temperature came down to normal with much sweating, and headache disappeared. Bowels moved several times.

Second day.—At 8 a.m. temperature 97.6°F., at 12 a.m. rose to 101°F. with shivering and headache, but

A serious danger is that the repeated failure to obtain permission for an autopsy will discourage efforts to get this permission on subsequent occasions; this is such a real danger that a very great effort should be made by the senior members of the staff to break the run of failures, and once this run is broken matters will be easier. If a 'tradition' can be established, it will usually be possible to get an autopsy whenever it is required. To show that this last remark is not just wishful thinking, we will give a concrete example.

Twenty odd years ago a tea-garden medical officer, realizing the importance of post-mortem examinations, attempted to obtain permission for an autopsy whenever a patient died in his hospital. He eventually obtained the permission from a coolie to do a post-mortem examination on her dead partner; there was a riot in the garden and the other relatives threatened to burn down the house and hospital. For a short time the hospital was boycotted, but its value was so obvious that it soon regained its popularity. A few weeks later a coolie died suddenly in rather doubtful circumstances; the doctor refused to sign the death certificate without a post-mortem examination, which was opposed, so he informed the police and naturally suspicion fell on all those who had opposed the post-mortem examination. The next time the doctor asked to be allowed to do a post-mortem examination on legal grounds, it was allowed and there was no riot. The tea company made certain allowances for funeral expenses; if a post-mortem examination was refused when the doctor asked for it, these allowances were not paid. So, by a process of legal and economic pressure the prejudice against autopsies was gradually

broken down. Care was taken to do the examinations with the least possible disfigurement to the body, and in time not only was there little opposition but there was often a demand for a post-mortem examination. This practice has passed into the hands of a second and now a third medical officer, both keen and intelligent men who have maintained this tradition, and to-day one can obtain a post-mortem examination on anyone who dies on these tea estates without any trouble.

In a town conditions are of course different, and the population from which a hospital draws its patients is so large that it would take much longer to establish such a tradition.

We agree with Dr. Tribedi that it is not so much legislation that is required as official support. It should, for example, surely be possible to limit the legal rights of the funeral societies. We know nothing of the legal aspect of the case but the societies must have been given some legal status, otherwise the hospital authorities would have no obligation to hand over the bodies to them. It should be possible to give the hospital authorities the right to do a post-mortem examination before handing over the body. In many hospitals in England, the patient's relatives are asked to sign a declaration that they will not oppose a post-mortem examination, before the patient is admitted to hospital; the question of introducing this practice in the large teaching hospital in India might be considered.

Special Article

AUTOPSY STUDIES IN INDIA

By B. P. TRIBEDI, M.B. (Cal.), D.B. (Lond.)

Professor of Pathology and Bacteriology, Medical College, Calcutta, and Bacteriologist to the Government of Bengal

THE president of the Indian Medical Association while discussing the dearth of medical researches in India (Roy, 1941) observed that the condition is such that 'any country ought to be ashamed and particularly India, whose genius and scientific talents are by no means wanting'. At the same conference, the vice-chancellor of the Andhra University said that in the progress of scientific medicine the contributions from Indians were not much in evidence (Reddy, 1941).

If this is so, we should take stock of the existing circumstances and try to realize the gravity of the situation. There is a general opinion amongst the medical public that India should take up post-graduate teaching more seriously and should provide greater facilities for research in the field of medical science. Several of our universities are moving in this matter. Whether we consider medical research, post-graduate or under-graduate teaching, or any scheme for the improvement of medical

study, the question of post-mortem material comes in the forefront.

Bluestone (1922) made the following significant statement, 'Broadly speaking, no hospital is larger than its pathological laboratory. The progressiveness of a hospital is in direct ratio to the laboratory spirit which it maintains'. In any pathological laboratory, the post-mortem examinations supply the bulk of the material for higher study. Hektoen (1926) pointed out that the hospital which neglects the autopsy thereby limits its usefulness; further, he found no need to waste words in an argument in favour of a proposition that necropsy percentage is an index of hospital efficiency, because it was so self-evident.

So far as India is concerned the position of necropsy studies is far from satisfactory. In order to get the exact state of affairs at the present time, we have collected figures from different medical educational institutions in India. We issued a request to the heads of the various teaching institutions in Bombay, Madras, Bengal, Bihar, U. P., Punjab, Delhi, and Assam to let us have the total number of deaths in the hospitals and the total number of post mortems done during 1930-39, a period of 10 years. Most of them were good enough to comply with our requests. The information obtained is given in the following tables:—

TABLE I
Showing the combined all-India figures of total deaths and number of post-mortem examinations done in various teaching hospitals during the period 1930-39

Names of institutions	Number of autopsies done		1939	
	Total number of deaths

10	Jackson Medical School, Jalpaiguri	1,828	46	2.5
PERCENTAGE OF AUTOPSY ON THE TOTAL NUMBER OF DEATHS DURING 1930-39 IN ALL THE INSTITUTIONS.				
		4.9

Figures from two institutions could not be included here, as we had no permission to publish them. The figures reported above cannot be taken as an absolutely correct index of the autopsy percentage, because these do not include all institutions in India, but it seems quite reasonable to accept the figures given above as a rough indication of the state of affairs. In table II, it will be seen that figures from at least one institution of most of the provinces were included which will thus enable us to form an idea of the condition of autopsies in the country as a whole. From the data given above we are in a position to say that during 1930-39 a period of 10 years post mortems were held in less than 5 per cent cases of total deaths in the

hospitals. Is this number of post mortems sufficient for the teaching and progress of scientific medicine in India?

Christian (1926) while discussing the points for selecting a hospital for an internship described the various groupings of hospitals as done by the American Medical Association. An institution may be class A, so far as the efficient treatment and comfort of the patients are concerned, but, so far as the facilities of teaching, the same institution may be of class C, i.e., though the institution has the best arrangements for treatment, as a teaching institution, it may be far from satisfactory. Christian further discussed what should be the criterion of a class A teaching institution. He pointed out that 'for a definite educational value, there must be instruction and guidance. The men on the staff are more important than the equipment of the hospital, and the number and type of the patients. They must be willing to instruct the interns; they must be willing to spend time in the hospital engaged with the interns in the study of patients; they must be well trained themselves and they must know how to teach'. Nothing could be more true and these points should be impressed upon those who guide the medical institutions in our country. He further observed 'looking about for any other criterion it has seemed to me that the number of necropsies obtained in patients dying in the hospital is perhaps the best single index of professional efficiency of the hospital, of the amount of work devoted to the study of patients by members of the staff, of the eagerness of the staff to learn, and its teaching abilities. In my opinion, who has studied his patients conscientiously and has watched the progress of the disease from day to day, who has discussed the disease and its manifestations in the patients with the interns, who is sincerely desirous of learning more of the medicine, is the physician who makes every effort to secure permission for necropsy in all

Graphical representation of total number of deaths and necropsies in India during the period 1930-39.

fatal cases and is keenly interested in what is found. When such men make up the staff of any hospital, necropsy permits are sought in all fatal cases and obtained in good number; and hence the percentage of necropsies obtained in any hospital forms a very good index of the professional efficiency of the institutions and the desirability of that hospital as a place of an internship'.

Christian is further of opinion that any hospital in which the necropsies are 25 per cent or more of the number of deaths might be regarded as a desirable place for an internship. If we judge the Indian hospitals according to Christian's standard where do we stand?

Now let us examine how autopsies can be obtained, *viz.*, by (a) state legislation, (b) voluntary permit, (c) post-mortem examination done on unclaimed bodies. In India, so far as voluntary permits are concerned, it is almost negligible and there are no state laws to encourage diagnostic post mortems. So, at the present moment, we have to depend mainly upon the unclaimed bodies. The 5 per cent deaths that we are getting for necropsy now is due to the above fact. Unclaimed bodies, *i.e.*, patients picked up from the streets, street beggars and extremely poor people who could not afford to meet the funeral expenses, are being disposed of by the hospitals as they like. So it appears that at present we have to depend upon deaths of a class of people whose standard of living is lowest. It is expected that with the general rise in the standard of living in future, we may not have such unclaimed bodies as we are getting now. In that case even this extremely low figure of 5 per cent is bound to come down. To make things worse, at the present moment the progress of scientific medicine is being attacked from another direction. There are religious and communal bodies whose functions include looking after the unclaimed dead of their community. In Bengal, Christians and Muslims have such organizations which generally take away all the unclaimed bodies. So the bulk of the dead bodies required by the institutions is supplied from the unclaimed Hindu bodies. Recently, the Hindus have also started an organization to take away all the unclaimed dead bodies. The result is that the teaching institutions are faced with a very serious situation. In the Campbell Medical School Hospital, Calcutta, with an average of about 2,500 annual death rate, last year there were only two post mortems (personal communication). If this state of affair continues what will happen to medical education?

What is the argument of these communal organizations in taking away unclaimed bodies? Obviously, it is the desecration and mutilation of the dead. I am not concerned with the anatomical dissection, but in cases of diagnostic necropsies the question of mutilation should not come in. The communal organizations may be

assured that the post mortems are conducted by specialists who have had special training and experience in the subject, and that they are conducted with proper respect for the dead. It can be compared with a surgical operation. After the autopsy, the dead bodies are finally neatly made up; this practically rules out the question of disfigurement.

When we consider that necropsies are done for the sake of enhancing the knowledge of a science which aims at the good of mankind, no religion can reasonably stand against such a step. Does not religion stand for the good of humanity? Basu (1934) suggests state legislation for compulsory post mortem. This is rather too drastic a step and might affect very adversely the hospital attendance by the public. Even in the most progressive countries this sort of legislation could not be imposed, so in a backward country like ours this is hardly possible. Moreover, those who will formulate such legislation will have to be convinced first, otherwise what chance is there of such a measure being passed through the legislatures? So the members of the legislature will have to be educated first before we can think of any legislative measure. With this idea we issued an appeal (Tribedi, 1940), which had very strong support from many scientific men of our country (personal communication and Gharpure, 1941).

The Editor of the *Calcutta Medical Journal* (1940) while very strongly supporting our contentions observed 'the of affording facilities for the growth and development of medical science rests on those who are at the helm of administration and their actions should be actuated by no other consideration than advancement of medical education and improvement of the health of the country. It is not necessary to enact any legislation to this end. So long as the profession is assured of their good will, moral support, and active co-operation, they will be able to make better headway. To this end, with proper training, there should not be much objection from the public. When the people of the country could be trained to acquiesce themselves to medico-legal post mortems, there is no reason why they will not submit to medical post mortems, if the subject is well explained to them'.

Education of the public is essential, but who is going to educate them? Certainly the medical men of the country are the people to take up this work. The heads of the various departments must make it a point to see that the autopsy figures are increased. Christian (1926), as reported above, has put it in the best way. Physicians and surgeons who are responsible for the running of their own unit must see that all those who work under them, the resident medical officers, the interns, and the nurses, be all inspired and taught about the technique of getting voluntary permits. The initial movement must start at the hospitals.

It is worth narrating a very recent incident in our hospital which should be an eye opener to everybody.

On 18th March, 1941, a girl of nineteen was admitted for progressive enlargement of the liver and fever with jaundice. The enlarged liver gradually filled up the whole of the abdomen and after a month in the hospital the girl died. The chief of the unit where the girl was admitted was very anxious to learn something about the case. All the time during the child's illness the staff used to say to the parents that they were doing their best but they were in the dark. The parents were satisfied that the hospital staff were doing their best. They were heard to remark on many occasions while they came to visit the child—"Oh, they are doing their best because whenever we happen to be near the bed we find how anxious the doctors are about our child". When the child died, the chief spoke to them about making a small incision in order to learn something about the case as he was in the dark. The mother and father replied "Doctor, when you have done so much for our poor child, we are willing to help you in increasing your knowledge, so that you might gain something which may go to cure some other child", but they gave two conditions, *viz.*, the body must not be removed to the mortuary and the operation must be done by the chief himself. So the chief got one of the most instructive cases.

This incident is very significant. The one fact that made the parents agree was that they were impressed that the hospital did so much for the child. When the request for an incision came, it came from a group of friends. This fact is of the utmost importance for getting a voluntary permit. Everything depends upon the sympathy, tact and friendliness that are exhibited by the hospital staff to the sick and their relatives. If the relatives feel that the patient while alive was not treated properly and not well looked after, and that the relatives were not treated with sympathy, it will be useless to talk about a post mortem. Outside the hospital, the education of the public will have to be done by the family doctor. We gave the details of the scheme in the previous publication (Tribedi, 1940). These doctors in their student days, if they had proper inspiration from their teachers, are bound to get autopsy-minded throughout their careers. So it is evident that in obtaining voluntary permits, success depends upon the type of teachers that an institution has got. Need they be reminded 'the greatest diagnosticians of the present and the past generations have been those who spent years studying their fatalities at the autopsy table'?

The state also has a tremendous amount of responsibility in this matter, specially in a country like ours where the general standard of education is so low. As has been pointed out before, strict legislation is not always very helpful, but there should be sufficient gesture from the state that they encourage necropsies. In medico-legal cases, the state compels an autopsy, because it is the duty of the state to detect and punish the criminals. If we admit that scientific progress is similarly a state responsibility, it is expected that the state also will help us in this matter. For instance, in our country the state should not allow the unclaimed

dead to be taken away from their hospitals by communal organizations, if an autopsy be desired by those who treated that patient. If the communal organizations must take responsibility of the disposal of those unclaimed dead ones, they can be easily asked to take over after the autopsy has been performed and the body is satisfactorily reconstructed.

This is not much that we ask. For the progress of medical science, the government of the country must co-operate with the scientists. The medical science is not solely a test-tube phenomenon. Our programme of work is different from the physicists and chemists in this respect. We must get materials in the living and in the dead to work upon. We medical men are entrusted with the responsibilities of keeping the nation healthy and fit. If this is so, we have every right to expect help from those who can render it for the fulfilment of our mission. We hope our appeal will not go in vain.

Our grateful thanks are due to the principals of the medical colleges and schools who have very kindly responded to our request in furnishing the figures reported in this article.

THE SIXTH MAHARASHTRA AND KARNATAK PROVINCIAL MEDICAL CONFERENCE, POONA

The Sixth Maharashtra and Karnataka Provincial Medical Conference will be held at Poona under the auspices of the Poona Branch of the Indian Medical Association on the 13th, 14th and 15th October, this year. The main subject for discussion is 'Blood-pressure in health and disease'. Papers on other medical subjects will also be read and discussed. An exhibition of medical products, surgical appliances and interesting specimens is being arranged. All medical practitioners in the province are cordially invited to attend the conference.

DRUG MANUFACTURE AND RESEARCH WORKERS

In order to establish closer co-operation and co-ordination between the manufacturers and research institutions, the Indian Chemical Manufacturers' Association has approached important Universities in India carrying on research with a request to include representatives of manufacturers of chemicals and drugs on the Advisory Boards of the Universities. It is pointed out that association of manufacturers with Advisory Boards would enable them to give their suggestions about researches that would be useful to

SEPT., 1941]

the industry, as it often happens that researches are being carried out on products which are already being manufactured in the country or which could not be economically manufactured. Moreover, the manufacturers would be able to keep themselves in touch with the researches that are being carried out in the laboratories under the Universities.

DRUGS AND CHEMICALS

THE BOMBAY GOVERNMENT have arranged for the production of the following medicinal drugs and chemicals, under the guidance of their industrial research chemist, to meet the large demands of the Supply Department:

Phosphorus, tartaric acid, potassium perchlorate, iodine, strontium carbonate, and carbon bisulphide.

ECONOMY IN THE USE OF DRUGS IN WAR TIME: MEDICAL RESEARCH COUNCIL: THERAPEUTIC REQUIREMENTS COMMITTEE

TABLE I

Drugs which are at present either (1) regarded as essential, or (2) readily available

Acacia	Amylis Nitris	Calciferol
Acetarsol	Amylocainae Hydrochloridum.	Calcii Carbonas
Acidum Acetyl-salicylicum.	Anethum †	Calcii Chloridum
Acidum Ascorbicum.	Aneurinæ Hydrochloridum.	Calcii Hydroxichloridum.
Acidum Chromicum (Chromii Trioxidum).	Aniline Dyes, Bordcaux B, brilliant green, crystal violet, fuchsine, gentian violet, malachite green, methyl violet and scarlet red.	Calcii Lactas, Calcii Sulphas Exsiccatus, Calx Chlorinata, Campiiora Carbacholum, Carbamide (Urea), Carbo Activatus
Acidum Hydrochloricum.	Apomorphinæ Hydrochloridum.	Carbonei Dioxidum.
Acidum Hydrocyanicum.	Areca	Carbonei Tetra-chloridum.
Acidum Mandelicum.	Arecolinae Hydrobromidum.	Cardamomum
Acidum Nicotinicum.	Antimony Compounds.	Catechu
Acidum Phosphoricum.	Apomorphinæ Hydrochloridum.	Cera
Acidum Salicylicum.	Areca	Chiniosonum
Acidum Sulphuricum.	Argenti Nitratas	Chloralis Hydras
Acidum Tannicum	Argentoproteinum	Chloramina
Acriflavina	Arseni Trioxidum	Chlorbutol
Adeps Lanæ *	Atropina and its salts.	Chlorinated Xyl-enol.
Adrenalinæ, its salts and esters.	Atropinæ Methyl-nitras.	Chloroeresol
Aether	Balsamum Peru-vianum.	Chloroformum
Aethylis Chloridum.	Barbitonum	Chondrus †
Aethylmorphinæ Hydrochloridum.	Barbitonum Soluble.	Chlormii Trioxidum (Acidum Chromicum).
Allobarbitonum	Barii Sulphas	Cinchophenum
Aloe	Belladonnae Folium.	Coca †
Alolinum	Belladonnae Radix	Cocaine and its salts.
Alumen *	Benzocaina	Codeina
Aluminii Acetas *	Benzoinum †	Colchici Cormus †
Aluminii Hydroxidum *.	Benzylis Benzoas	Colchici Semen †
Aminophylline	Betanaphthol	Colocynthis
Ammonii Carbonas.	Bismuthum Pra-cipitatum.	Colophonium †
Ammonii Chloridum.	Bromethol	Creosotum †
Ammonii Phos-phas Acidus.	Calamina	Cresol
Amphetamina		Creta
		Cupri Sulphas

* With restrictions as to the method of manufacture or under Government control.

† Production in the United Kingdom or Empire should be encouraged.

TABLE I—concl'd.

Derris	Liquor Ferri Perchloridum.	Pix Liquida
Diamorphinæ Hydrochloridum.	Liquor Formaldehydi.	Plumbi Acetas
Digitalis	Liquor Glycerylis	Plumbi Monoxidum.
Digoxinum	Liquor Hydrogenii Peroxidi.	Procaine Hydrochloridum.
Diodone	Liquor Picis Carbонis.	Pyroxylinum
Dithranol	Emetina and its salts.	Quassia
Ephedra †	Ephedrina and its salts †.	Quinidinæ Sulphas
Ergot Alkaloids	Magnesii Carbonas.	Quinine Salts
Ergota †	Magnesii Oxidum	Rosorcinol
Extractum Fellis Bovini.	Magnesii Trisilicas.	Rheum
Extractum Pituitarii Liquidum (and preparation for intra-nasal insufflation).	Menthol †	Saccharinum Soluble.
Extractum Suprarenali Corticis.	Mepacrinæ Hydrochloridum.	Scoparium
Extractum Thyroidei Liquidum.	Mepacrinæ Methanesulphonas.	Senna
Ferri Carbonas	Mersalylum	Sinapis
Ferri Perchloridum.	Methylis Salicylas	Soaps *
Ferri Sulphas	Methylthioninae	Soda Lime
Ferrum Redactum.	Chloridum.	Sodii Aminarsonas.
Fluoresceinum Solubile.	Morphina and its salts.	Sodii Bicarbonas
Gelatinum	Oleum Anethi †	Sodii Carbonas
Glycerylis Trinitras.	Oleum Anisi †	Sodii Chloridum
Gold Compounds	Oleum Cadinum †	Sodii Diphenylhydantoinas (Dilantinum Soluble).
Guaiacol	Oleum Caryophylli	Sodii Iodidum
Heparin	Oleum Cinnamomi	Sodii Nitris
Hexamina	Oleum Eucalypti	Sodii Phosphas
Hinoxobarbitonum	Oleum Hydnocarpis	Sodii Phosphas Acidus.
Hinoxobarbitonum Solubile.	Oleum Iodisatum	Sodii Salicylas
Hexylresorcinol	Oleum Limonis †	Sodii Sulphas
Histaminae Phosphas Acidus.	Oleum Menthae	Sodii Thiosulphas
Homatropina and its salts.	Piperita †.	Stannum
Hyoscina and its salts.	Oleum Ricini	Stannii Oxidum
Hyoscyamus Muticus † (for manufacture of atropine).	Oleum Terebinthinae †.	Stibophenum
Kaolinum	Oleum Theobromatis.	Stilbcestrol
Lead Salts	Oleum Vitamina-tum.	Stramonium †
Leptazolum	Opium	Strychnina and its salts.
Liquor Calcis Sulfuratae.	Orthocaina	Sulphanilamidum
Liquor Cresolis Saponatus †.	Oxygenium	Sulphapyridinum
	Pamaquinum	Sulpharsphen-amine.
	Pancreatinum	Sulphathiazole
	Papainum	Sulphur
	Paraldehydeum	Suraminum
	Pentobarbital Sodium.	Theobromina
	Pepsinum	Theobromina et Sodii Salicylas.
	Phemitonum	Theophyllina
	Phenacetinum	Theophyllina cum, Aethylene-diamina.
	Phenobarbitonum	Thymol †
	Phenobarbitonum Solubile.	Thyrodeum
	Phenol	Thyroxinsodium
	Phenolphthaleinum	Totaquina
	Phenolphthaleinum p-hydroxy-	Tragacantha †
	its salts.	Trinitrophenol
	Phystostigminæ Salicylas.	Tryparsamidum
	Pirevan	Urea
	Pix Carbonis Präparata.	Ventriculus Desiccatus.

TABLE II

Drugs which are essential for certain purposes but not for others, and in the use of which strict economy should be observed

Aeetonum *	
Acidum Aceticum	
Acidum Benzoi- cum.	
Acidum Boricum	Boric acid in boric lint is wasted. Reserve for cataplasma kaolini and eye lotions. In dermatological practice saline compresses may be used instead of boric fomentations, and for dusting powder boric acid may be replaced by zinc oxide, magnesium trisilicate or kaolin.
Acidum Citricum	Manufacture under Government control.
Acidum Lacticum	
Acidum Nitricum	
Acidum Oleicum	
Acidum Tartari- cum and its salts.	Raw material is imported. Production within the Empire should be encouraged.
Adeps Benzoin- atus *.	
Agar	Substitute:—Ispaghula. Agar should be reserved for bacteriological media. Production within the Empire should be encouraged.
Alcohol	Many tinctures can be replaced by concentrated preparations. Econ- omy is essential.
Amylum *	In dermatological practice substitute saline compresses for starch poultices, and for powders see remarks under boric acid.
Aurantii Cortex †	Countries of origin:—Spain, Sicily, Malta. Limited supplies are avail- able from the Empire at present.
Benzaminae Hy- drochloridum.	
Benzaminae Lactas	
Bismuth Salts	Reserve for the treatment of syphilis and tropical diseases. Substitutes (for gastro-intestinal conditions):— Aluminium hydroxide, chalk, kaolin, magnesium trisilicate.
Bismuth Salicylas	Reserve for the treatment of syphilis and tropical diseases. Substitutes (for gastro-intestinal conditions):— Activated charcoal, kaolin.
Borax	In dermatological practice reserve for unguentum aquosum. Glycerine of borax and honey of borax may be replaced by aqueous solutions of aniline dyes in the treatment of thrush.
Bromides	Strict economy is necessary.
Caffeina	Omit from compound tablets such as compound aspirin tablets.
Caffeina et Sodii Benzoas.	Amphetamine (benzedrine), leptazol (cardiazol) and nikethamide (cor- amine) are partial substitutes.
Capsicum	Countries of origin:—Nigeria, Sierra Leone, E. India. Restrict use of capsicum to manufacture of capsi- cum wool. Substitute:—Sinapis. Colonial varieties of capsicum may be obtainable.
Carbromalum	

* With restrictions as to the method of manufacture
or under Government control.

† Production in the United Kingdom or Empire
should be encouraged.

TABLE II—contd.

Caryophyllum	Countries of origin:—E. India, Zanzibar, Pemba, Madagascar. Reserve for distillation of the oil.
Cascara Sagrada †	Countries of origin:—Canada, U.S.A. Substitute:—Dithranol.
Chrysarobinum †	
Cinchona †	
Corpus Luteum	
Cyclopropanum	
Desoxycorticoster- oids	Extract of suprarenal cortex is in one and its free supply.
Dextrosum *	Reserve for injection.
Dextrosum Mono- hydratum *	Strict economy is essential.
Extractum Hepa- tis Liquidum	Importation of liver is under Govern- ment control. Injection therapy is more economical and effective than administration by mouth. Desic- cated stomach may be substituted for liver for oral administration.
Extractum Malti *	
Extractum Para- thyroidei (and parathyroid pre- parations for parenteral injec- tion).	
Ferri et Ammonii	Not the most economical form of iron: ferrous sulphate is cheaper.
Ferri Lactas	
Ferri Subchlori- dum Citratum.	Not the most economical form of iron: ferrous sulphate is cheaper.
Filix Mas	Reserve for use when other anthel- mintics are contra-indicated. Pro- duction in the United Kingdom should be encouraged.
Galla	
Glucosum *	Strict economy is essential.
Glycerinum	Substitutes are under investigation.
Glycyrrhiza †	Countries of origin:—Spain, Sicily, Italy, Iraq, U. S. S. R.
Hydrargyrum	
Hydrargyrum Am- moniatum.	
Hydrargyri Iodi- dum Rubrum.	
Hydrargyri Oxi- dum Flavum.	
Hydrargyri Oxy- cyanidum.	
Hydrargyri Per- chloridum.	Substitute:—A phenolic antiseptic of the chlorinated phenol type.
Hydrargyri Sub- chloridum.	
Ichthammol	
Injectio Hepatis	
Iodini †	Adequate supplies are available, but owing to shortage of alcohol, the use of alcoholic solutions of iodine must be greatly restricted. Substi- tutes:—Aqueous solutions of iodine, acrilayine, brilliant green, crystal violet, proflavine, and trinitro- phenol.
Ipecacuanha †	Galenic preparations of ipecacuanha such as expectorants and emetics are not essential and the crude drug should preferably be reserved for the manufacture of emetine.
Jaborandi †	Reserve for the manufacture of pilocarpine.
Jalapa	
Jalape Resina	{ Reserve for veterinary use. Countries of origin:—Mexico, India. Substi- tute:—Colocynth.

TABLE II—concl'd.

Lactosum	
Lævulosum	
Liquor Vitaminini A Concentratus.	
Liquor Vitaminini D Concentratus.	
Liquor Vitaminorum A et D Concentratus.	
Magnesii Chloridum.	Reserve for veterinary use.
Mel *	
Oestradiol, Oestriol, Oestrone and their esters.	
Oleum Arachis	
Oleum Chenopodiæ †.	In Great Britain reserve for veterinary use. Substitutes:—Carbon tetrachloride, thymol.
Oleum Gossypii Seminis.	
Oleum Hippoglossi	
Oleum Linæ *	Reserve for internal use in veterinary practice.
Oleum Morrhuae *	Substitute:—Oleum vitaminatum and veterinary vitaminized oils, as applicable to relieve scarcity.
Oleum Olivæ *	Arachis and other suitable vegetable oils are recognized as substitutes in official preparations.
Oleum Rapæ	Reserve for external use in veterinary practice.
Oleum Sesami	See under Oleum Amygdalæ.
Paraffinum Liquidum *.	Its use should be discouraged.
Paraffinum Molle *	
Parathyroideum	
Pilocarpina and its salts.	Substitute:—Physostigmine and its salts for most purposes.
Pituitarium	Including anterior lobe extracts.
Podophylli Resina	Restrict to Indian podophyllum.
Potassii Tartras Acidus.	See under Acidum Tartaricum.
Proactin	
Quillaia	Countries of origin:—Chile, Peru, India.
Santoninum †	Countries of origin:—U. S. S. R., Kashmir. Importation difficult. Substitutes:—Hexylresorcinol, phenothiazinc.
Sodii Benzoas	
Sodii Bromidum	
Sodii Citras	See under Acidum Citricum.
Sodii Lactas	Reserve for use as a glycerine substitute.
Sodii et Potassii Tartras.	See under Acidum Tartaricum.
Spiritus Aetheris Nitrosi.	Substitute:—Concentrated solution of ethyl nitrite.
Spiritus Methylatus Industrialis *	
Styrax †	Country of origin:—Asiatic Turkey. Wanted for compound tincture of benzoin.
Sucerosum *	
Syrups	The use of all syrups should be discouraged.
Syrups Ferri Phosphatæ.	Reserve for children.
Tinctures	Many tinctures can be replaced by concentrated preparations. Economy is essential.
Urginea	Importation difficult in war time.
Valeriana †	
Zinci Chloridum	
Zinci Oleostearas	

TABLE III

Drugs which are not essential and do not justify importation or manufacture for home use in war time

Drug	Substitute	Countries of origin
Acetanilidum	Acetylsalicylic acid or phenacetin.	..
Acetylcholine		
Acidum Glycerophosphoricum and its salts.	None necessary	..
Acidum Hydrobromicum.		..
Aconitum	Benzocaine for local application.	Germany, Switzerland, France.
Aethylenum		..
Alcohol Isopropylicum.		..
Amidopyrina	Acetylsalicylic acid, phenacetin.	..
Balsamum Toluatanum †.		
Betaine Hydrochloridum.		..
Bromosorum Buchu		
Calumba †	Quassia	E. Africa (Mozambique).
Cannabis Indica		India, S. Africa, Zanzibar.
Cantharis		U. S. S. R., Spain, Hungary, China.
Cantharidinum	{ Sinapis	
Carum †	Carum (dill).	Holland, Germany, China.
Cassia		
Coccus	Solution of Bordeaux B. Other good colours are available.	Canary Islands.
Copaiba	Hexamine, mandelic acid, scopolium, sulphaniamide.	Northern South America.
Coriandrum	Cardamomum	Morocco, U. S. S. R., India, Central Europe.
Cubeba		
Cusso	Carbon tetrachloride, male fern.	N. E. Africa.
Erythritylis Tetranitras Dilutus.		..
Ferri Arsenas	Ferrous sulphate with arsenic.	..
Ferri et Mangani Citras.	Ferrous sulphate	..
Ferri et Quinina Citras.	Ferrous sulphate	..
Ferri et Potassii Tartras.	Ferrous sulphate	..
Ferri et Strychnæ Citras.	Ferrous sulphate with strychnine.	..
Ferri Glycerophosphatæ.	Ferrous sulphate	..

* With restrictions as to the method of manufacture or under Government control.

† Production in the United Kingdom or Empire should be encouraged.

TABLE III—*contd.*

Drug	Substitute	Countries of origin
Ferri Hypophosphis.	Ferrous sulphate	..
Ficus	Therapeutic value doubtful.	..
Foeniculum †
Gelsemium	Synthetic analgesics.	U. S. A.
Gentiana †	Quassia	France, Germany, Spain. Almost unobtainable.
Hamamelis †	Tannic acid	U. S. A.
Injectio Ferri	Ferrous sulphate by mouth.	..
Krameria †	Tannic acid	Peru.
Linum	Cataplasma kaolini for poultices.	..
Lobelia †	Stramonium	Eastern U. S. A.
Lobelina	Nikethamide, leptazol.	..
Magnesii Sulphas	Sodium sulphate, of which very large supplies are available.	..
Methylsulphona!
Oleum Abietis	Any oil of pine	North-east U. S. S. R.
Oleum Amygdalæ †	All vegetables, oils and fats are under Government control. Arachis and other vegetable oils may be used if available.	..
Oleum Camphoræ Rectificatum.	Oleum terebinthinae. See Camphora.	..
Oleum Cardamomi
Oleum Cari	See Carum	..
Oleum Crotonis	Unnecessary oleum gaultheriae. Methyl salicylate.	..
Oleum Santali	Hexamine, mandelic acid, scopolium, sulphanyl-amide.	India.

TABLE III—*concl.*

Drug	Substitute	Countries of origin
Pelletierinæ Tan-nas.	Carbon tetrachloride, male fern.	Mediterranean countries.
Phenazonum	Acetysalicylic acid, phenacetin.	..
Potassii Bicarbonas.	Sodium bicarbonate.	..
Potassii Bromidum.	Sodium bromide	..
Potassii Chloras	Not essential	..
Potassii Citras	Sodium citrate	..
Potassii Hydroxi-dum.	Sodium hydroxide	..
Potassii Iodidum	Sodium iodide	..
Potassii Nitratas	Not essential	..
Potassii Perman-ganas.	Solutions of other permanganates.	..
Psyllium *	Ispaghula	Mediterranean countries.
Salicinum	Sodium salicylate	..
Salol	Indian podophyl-lum.	..
Scammonium	Urginea (Indian Sicily. squill) and other expectorants.	..
Scilla †	Senega	Canada, U. S. A.
Sodii Tauroglyco-cholas.	Ammonium car-bonate, ammonium bicarbon-ate, ammonium chloride.	..
Sparteina	Sodii Tauroglyco-cholas.	..
Strophanthus	Digitalis	Mozambique, Nyasaland.
Sulphonal	Extract of ox bile	..
Syrupus Ferri Phosphatis cum Quinina et Strychnina.	Tablets of Easton's syrup.	..
Talcum Purifica-tum.	Talcum. For substitutes see under acidum boricum.	..
Tamarindus	..	India, Burma, W. Indies.
Taraxacum †

TABLE IV
Identical substitutes of British manufacture

Drug of foreign origin	Identical substitute	Drug of foreign origin	Identical substitute	Drug of foreign origin	Identical substitute
Acaprin	Pirevan.	Eumydrin	Atropine Methyl-nitras.	Myosalvarsan	Sulpharsphen-amina.
Anæsthesin	Benzocaine.	Euphyllin	Theophyllina cum Aethylenediamina (aminophylline).	Nembutal	Pentobarbital Sodium.
Atebrin	Mepacrineæ Hydro-chloridum.	Evipan and Evi-pen Sodium.	Hexobarbitonum and Hexobarbi-tonum Solubile.	Novocaine	Procaine Hydro-chloridum.
Atophan	Cinchophenum.	Fouadin	Stibophenum.	Perabrodil	Diodone.
Atoxyl	Sodii Aminarsonas.	Germanin	Suraminum.	Plasmoquin	Pamaquinum.
Avertin	Bromethol.	Luminal and Luminal Sodium.	Phenobarbitonum and Phenobarbitonum Solubile.	Prominal	Phenitonum.
Bayer 205	Suraminum.	Medinal	Barbitonum Solu-bile.	Prontosil Album	Sulphanilamidum.
Benzedrine	Amphetamine.			Protargol	Argentoproteinum.
Cardiazol	Leptazolum of home manufac-ture.			Salyrgan	Injectio Mersalyli.
Coramine	Nikethamide.			Uroselectan B	Iodoxylum.
Dial	Allobarbitonum.			Veronal	Barbitonum.
Dionine	Aethylmorphinæ Hydrochloridum.			Yatren	Chinicfonum.
Doryl	Carbacholium.				

Public Health Section

PHYSIOLOGICAL HYGIENE

FROM a public health point of view, the factors controlling human health can be classified under two main heads—internal and external. The internal factors include heredity and physique, the latter being determined largely by nutrition, and the external factors physical and social environments.

Individual health is to a great extent dependent on the individual's hereditary characteristics—physique, intelligence and aptitude. Similarly, racial health is, according to recent trends of thought, dependent on the application of certain eugenic methods. In fact, the science of eugenics is a 'study of the agencies under social control that may improve or impair the racial qualities of future generations', either physically or mentally; thus by an improvement of the social environment, the most important environment of man, the inherited qualities of the race are given the most favourable opportunities for the development of physical and mental health.

With regard to physique, it is well recognized that it is largely influenced by nutrition and this factor has been thoroughly investigated and the knowledge gained has been extensively applied in public health programmes. Thus, nutrition occupies a unique place between heredity on the one hand and environment on the other, influencing both equally forcibly.

Analysing the various external factors, one finds that nutrition, parental care during childhood, and good housing and sanitation are amongst the most important. Of these, undoubtedly nutrition again is the first and foremost individual factor in human health. Though some Swedish and Indian experts consider that even with a 'poverty' income adequate nutrition can be obtained if only the individual is taught how best to utilize the amount for purchasing the most nutritious foods, it is now admitted on the basis of extensive researches that the greatest single factor for the improvement of individual health (synonymous with national health) can only be a change in the economic system, whereby every individual in all classes of society is provided with an adequate minimum income which will enable proper and adequate nutrition to be obtained. The modern nutritionist thus defines nutrition in ideal terms rather than in terms of compromise.

With reference to other aspects of human environment, such as the physical environment, recent research has established their usefulness in the maintenance of the health of man. The work of Shapiro and Hulse* on the Japanese

immigrants at Hawaii has shown, by quantitative anthropometric measurements, that even the dynamic human structure, in as short a time as one generation, is plastic to the influences of the physical environment.

The physical influences responsible for human comfort can be said to be the external temperature, humidity, air velocity and radiations from surrounding bodies. The researches of Herrington and his associates at the John B. Pierce Laboratory in New Haven, Connecticut, on 'partitional calorimetry' have clarified many points on exchanges of heat in the human body under various conditions, and those of Cecil Drinker* at the Harvard School of Public Health, Boston, have gone a long way towards bringing about a better understanding of the physiological principles in public health. The work of Yaglou† on the natural and artificial air conditions and that of the American Society of Heat and Ventilation Engineers at their Pittsburgh experimental station, who have evolved an 'effective temperature' chart that gives a numerical value to the combined air conditions, have widened our outlook on the scope and usefulness of air conditioning. Dufton's‡ 'equivalent temperature' index and the eupathtioscope are tending to replace Leonard Hill's earlier katathermometer. These are only some of the instances where Science has attempted to conquer Nature, to the greater comfort and better health of the individual.

Occupation, the next social environment, is accepted as a factor of major importance. Occupation in relation to health has been the subject of intense scientific study since the last European war. These studies have gone to prove that physical and mental environment is as important as the constitutional make-up of the individual worker. Year by year, more information on industrial occupations is being accumulated. The industrial Fatigue Research Board (now known as the Industrial Health Research Board) have gone into minute details of the health and efficiency of the industrial worker under various conditions; fatigue has been eliminated and the physical efficiency of the workers enhanced to a great extent as a result of the proper control of work spells and rest pauses based on scientific study. The multiple shift system that is being followed under emergency conditions, as at present, is an outcome of the extensive researches done in this connexion.

Apart from the researches of the Industrial Research Board, referred to above, modern industrial and warfare organizations have made it necessary for the scientist to investigate in detail certain biological problems; aviation medicine, for example, is to-day a well-recognized specialization brought into being to deal with the hazards peculiar to rarefied atmospheres and the high speed of aeroplanes. The great variety of synthetic chemicals that are manufactured has made industrial toxicology a prominent subject in industrial medical practice, and in some instances legislation has been introduced for the prevention of certain industrial hazards. Psychological medicine has also been called upon in the case of occupational selection and vocational training of the industrial worker and the treatment of his 'accident neurosis'.

Thus it is that the workers on many diverse subjects have in recent years played their parts in achieving the common object of enhancing the individual and national health by researches on the ever-changing human environment. These researches are now recognized as forming part of the new field of physiological hygiene.

It will be seen from this short résumé that physiological hygiene has developed into a vast science which can no longer be ignored by the sanitarian. It is on account of the recognition of its great importance that leading universities have created separate departments of physiological hygiene for the training of public health officers. The London School of Hygiene and Tropical Medicine has included the subject for the D.P.H. of the London University, and the American Universities have also endorsed its importance by giving degrees and instituting research courses on the subject.

In India, the All-India Institute of Hygiene and Public Health has followed the excellent example of the English and American universities and has recently, under the inspiration and guidance of its new director Dr. J. Grant, organized a physiological hygiene section. This we are sure will enhance the reputation and usefulness of the institute. The importance of this section can best be realized when it is remembered that the environment in the tropics differs from that in the temperate climates and that many of the advances made elsewhere cannot be applied directly in tropical countries, such as India, without further investigations on the subject. As an example may be mentioned the oft-quoted 'effective temperature index' of the American Society of Heat and Ventilation Engineers which is accepted as a criterion in many countries of the world. The recent investigations of the physiological hygiene section of the All-India Institute of Hygiene and Public Health have shown that this index is not completely applicable to Indian climates. The mechanism of heat regulation, as revealed by studies in experimental chambers in colder

AVAILABLE LIGHT IN A PUBLIC BUILDING

By G. SANKARAN, M.B., B.S.
and

D. N. MULLICK

(From the Physiological Hygiene Section of the Department of Biochemistry and Nutrition, All-India Institute of Hygiene and Public Health, Calcutta)

Purpose of the study

RECENT researches show that nearly 60 per cent of human actions are based on visual impressions. These impressions are in turn dependent on lighting, either natural or artificial. One reads in an authoritative League of Nations' publication 'Suitable lighting leads to cleanliness of work places, postponement of fatigue, prevention of accidents, easier discipline and control, limitation of waste and better quality of work with more rapid production'. In addition, light influences people's frame of mind. Darkness and semi-darkness are associated with gloom and depression, whereas light creates an atmosphere of brightness, cheerfulness and high spirits. Alternatively it is common experience that damage to eyesight or eye strain and fatigue with consequent inefficient and slow work is caused by insufficient light at places of work. It is usual in building practice to design in such a way as to provide enough entry of natural light. This is stated as that 20 per cent of floor space should constitute the area necessary for windows, and is approved by public health engineers and officers. It of course goes without saying that all important public buildings have been planned in conformity with this principle. Even so have we any justification in assuming that at all places of work in these buildings enough light is provided according to the standard minimum illumination worked out at 10 foot-candles for office work and from 20 to 25 foot-candles for more delicate work as in laboratories? As far as we are aware no data on this point are available for any of the important buildings in India such as schools, factories, museums, institutes, etc. It was therefore decided that study of the illumination of a modern building will be useful and form a first contribution from the department of physiological hygiene. The results obtained, as will be seen later, are quite unexpected and seem to

(Continued from previous column)

climates, is probably not applicable in its entirety to Indian conditions where the evaporative heat loss from the body is at work during the major part of the year, and where acclimatization has also to be taken into account.

By studying the conditions as they exist in the tropics, it will be possible to collect data on which new formulæ can be worked out or existing formulæ modified to suit these conditions.

justify a more systematic study of the problem in all public buildings. As it is we feel that enough light is not provided for the use of a large number of important workers in most important buildings devoted to work and study.

Scope of the study.—The observations are limited to 30 places of work in one building chosen for investigation. These observations were further restricted to office, record, labora-

up to 50 foot-candles and its sensitiveness is about 0.5 foot-candle. A cover for the sensitive cell is provided which permits of a limited fraction of light to its surface and enables the instrument to be used up to ten times the normal range, or 500 foot-candles. The instrument is light and portable and is placed on the table or work bench where illumination is to be measured and readings are made immediately.

tory, library, and artist's room. The illumination in these rooms was tested at the following hours 7 and 10 a.m., 12 noon, 2, 4, 6 and 8 p.m.; 210 observations were made in the month of March 1940.

Methods.—All the illumination measurements were made by Weston's photronic metal oxide rectifier type of self-exciting cell, Model E 703. It is named a 'lightometer' by the makers and has an indicator which reads directly in foot-candles. The normal range of the instrument is

Results.—The data obtained are collected in the table attached. The figures are foot-candles of light available at the hours mentioned.

Discussion

(1) *Office.*—For office work the minimum light requirement is given as 10 foot-candles, and for fine work as 20 foot-candles. Considered from this standpoint, out of 77 observations at 11 positions, only 19 observations are above 10 foot-candles and 9 above 20 foot-

candles. It is particularly pointed out that the cashier and the despatcher who for obvious reasons should be provided with at least 10 foot-candles or better 20 foot-candles, only have the ridiculously low figures of about 3 foot-candles all the time they are at work. If they make mistakes they have justification for it.

It is also to be noted that after darkness has set in the illumination under artificial light is at the extremely low value of from 0.5 to 1.5, suitable only for corridors and other such places. Yet members of the office staff quite often work late into the night.

(2) *File room.*—Here again the place is very badly lighted. An observation as high as 10.5 foot-candles was only once obtained. Needless to say efficient filing of records is not possible under such circumstances.

(3) *Library.*—The table where reading is done is below standard requirements. At night the light values are from 0.5 to 1.0. This should give rise to severe eye strain and is certainly unhygienic. Many have felt difficulty in reading in the library and it never struck them that it would be profitable to investigate the cause. With the library open till 9 p.m. the question of better illumination should immediately be considered.

(4) *Laboratories.*—The south end of the work tables where in fact the workers usually work is inadequately lighted. Work is impossible at night with only 1.0 foot-candle.

(5) *Artist's room.*—This is the only place with proper illumination and even here at 7 a.m. it is low.

In giving standards of lighting required for various kinds of work we are dependent on the results obtained in European countries, England for example. It is doubtful if these standards are applicable to India. In a discussion of the thermal comfort zone for men the standards necessary in sub-tropical climates worked out in those countries is by no means applicable here.

We have evidence of the phenomenon of acclimatization; in a similar manner there is every possibility of adjustment to illumination sensitivity as well. In our climate we are provided with far more intense natural light for much longer periods of the day than obtains in Europe. It is just possible that we need more light for our work than those in sub-tropical or arctic regions will require. This is a problem needing study before recommendations can be made.

Conclusion.—It appears that while window-space is of proper amount, enough light is not available for ensuring efficiency at many places in the building investigated. It may be that no rational or scientific methods have been followed in locating the tables of workers. It may be that partitions or almirahs are placed in the wrong place and obstruct light. The artificial light fittings at present provided are quite inadequate for any kind of work.

Discussion.—The need for provision of increased light is evident particularly in the evenings and at night. A good deal of work has been done on the (1) efficiency of work, (2) turnover of production, and (3) freedom from mistakes in well-lighted buildings and factories. This suggests the desirability of considering methods for provision of increased lighting. It would involve increased outlay of capital in providing powerful lighting installations as well as increased expenditure on fuel for lights—paraffin and gas or electrical energy. To administrators the question that will arise is whether this extra expenditure is justifiable. In an investigation conducted in a tile-pressing factory 'the old illumination of the order of 1.2 foot-candles was increased to about 3.5 foot-candles or roughly three times for about 80 per cent increase in the electrical energy consumption. The increased consumption however resulted in a 6 per cent increase in efficiency and turnover. The lighting cost frequently does not exceed 1 per cent of the pay roll. The increased illumination appears to be justified on economic grounds alone, apart from the satisfaction which it affords the workers'.

These figures were obtained at a time when production of lights had not progressed much beyond Edison's original discovery of the glowing bulb containing a charred bamboo fibre. As recently as 1932 great strides have been made in the technique of light production with discharge lamps of mercury and sodium. The future of illumination seems to be in this direction for several reasons. One reason is that three times more light is produced for the same amount of wattage from discharge lamps compared with that from filament lamps. This will be particularly appreciated with higher wattages essential for modern times. During the last two years another major revolution in ideas on illumination has taken place in the introduction of what is known as 'blended lighting'. In this system mercury vapour lamps and sodium vapour lamps are fixed under the reflector with the result that the mixture of red end and blue end of the spectrum give a bluish-green light indistinguishable from natural light. At this wave-length the retina is most sensitive so that with this blended light far less intensity of light is necessary than with filament lamps. It is a further advantage that there is less strain on the eyes.

The latest improvement is the fluorescent discharge lamp, where use is made of ultra-violet energy which by itself is invisible and absorbed in the glass wall. By lining the inside of the lamp with fluorescent material, the wasted ultra-violet energy produces the valuable fluorescent light and thus further increases the efficiency of the discharge lamps.

One almost feels that we have reached the ideal: It was thought so even when ordinary electric lights banished the evil-smelling and smoky oil and gas burners.

MATERNITY AND CHILD WELFARE**THE SCHOOL TEACHER AND CHILD WELFARE**

By L. S. GHOSH, W.M.S.

(From the Department of Maternity and Child Welfare,
All-India Institute of Hygiene and Public Health,
Calcutta)

IN recognition of the fact that the civic or community standard of living cannot be higher than that desired and practised by the great bulk of the individuals making up the community, the term 'health education' has come into common use to cover instruction in both the personal and community aspects of hygiene.

The child in school becomes for the first time a member of a group other than his home circle. Through his contacts with other children and his teachers during play and study he meets many of the problems which later on a larger scale he will face as an adult. What is it possible to teach him?

He can be taught what each citizen, both in his home and in his outside sphere of activity, can do to make health appreciated. He can be taught to realize that health is a contribution towards success in life, family happiness and the enjoyment of good civic amenities in his village or town. The older child can be taught that good health is cheaper than sickness, that permanent disabilities which follow many diseases limit the opportunities and earning capacity of the victims, that the protection of health is not an expensive fad but an economic asset, that money well spent by the community for this purpose saves the individual's purse. The school child can also be trained to habits which will automatically make him desire and demand a more healthy way of living for himself and his community.

The close relationship between the civic and personal aspects of hygiene can be seen in the following three examples:—

Let us take first the habit of spitting. Only by training the individual not to spit on floors and pavements can the cleanliness of houses and streets be improved and something effected towards the control of diseases, like tuberculosis, which are spread by germs in the sputum. Laws laid down by local bodies can be rendered quite useless by the individual consistently disregarding them.

Secondly, let us consider the ever-running water tap. Enormous wastage of water occurs by public taps and taps in houses constantly running. Water is precious in most parts of India, but only by personal habitude to turning off taps after use can water be conserved for drinking and bathing and domestic purposes. Many buildings and structures also will be saved from unhealthy dampness and infection by the proper handling of water taps.

Thirdly, let us consider the problem of unclean food sold in the streets. The child in

whom is created a distaste for food exposed to flies and dust, or food carelessly handled, will tend to carry that distaste into adult life. Conditions for the improvement of preparation and public sale of food and sweets are more likely to develop quickly by the individual refusing to buy anything but clean food than by regulations or legislation.

That is the case for the teacher. But is the future of health training in the teachers' hands alone?

It would be a mistake to imagine that it is—the home must be considered to influence the child at least as much as the school. The greatest difference between the two influences is that that of the teacher in India is still largely bookish and theoretical, while in the home, habits are insensibly formed by practice and custom. To talk in school of clean food, when daily the child sees no precaution taken at home, can leave little bias in favour of hygienic practice.

To be successful, therefore, health education in schools must mean—(1) practice rather than lessons with the child as the individual and the class as the community; (2) that a teacher has some knowledge of and contact with the parents and home of the child; (3) that the child is given opportunities to visit the various institutions and organizations set up by the local body for purposes of hygiene, such as the water works, sewage works, the refuse disposal, food shops, and, in large towns, museums where models are shown.

Let us consider how the first requirement can be met, that is, how hygiene can be taught by practice rather than by lessons from a book. This routine exacts a great deal of tact and enthusiasm from the teacher and it necessitates the following of a carefully planned scheme of work.

Each child should make and keep a health diary. The type of diary may vary with the economic circumstances of the child and the type of school, but in its simplest form it need only be a long sheet of white paper pasted on cardboard and ruled into vertical columns, each one representing one phase of hygienic practice; for example, 'I bathed and turned off the water tap afterwards'; 'I cleaned my mouth'; 'I brushed my teeth'; 'I used the latrine and washed my hands afterwards'; etc. Horizontal lines are drawn to divide the columns into daily compartments, a date for each day being written down the left-hand side of the diary.

The teacher, as soon as the child arrives in school, must examine him and allow him to fill in his diary. She must scrutinize his hands, hair and general toilet and for each item on the diary complied with, a disc of red paper or a mark made with red pencil can be put in the corresponding compartment. Fifty such red marks earn a golden disc or a yellow mark and rewards either in the form of a post of responsibility in

one case, within 72 hours in 2 cases, and in the remaining 4 cases after 4, 6, 7, and 24 days, respectively.

There is positive evidence from the above summary to show that the chances of recovery are adversely affected by age, severity of disease; late diagnosis, and the presence of a coincident grave illness, and that death may occur before M. & B. 693 can be therapeutically effective. Although only one patient died within 24 hours, 2 others were moribund on admission and treatment was given without hope of success. At that time M. & B. 693 soluble was not available, but it is unlikely that the patient who succumbed in 10 hours could have been saved by any treatment; in the 2 other cases parenteral M. & B. 693 might have succeeded where oral administration had failed. Early administration of M. & B. 693 soluble might also have been of value in some of the other cases. One patient received an inadequate initial dose (3 tablets, *t.d.s.*) and 3 other cases might have stood a better chance of recovery had four-hourly administration of the drug been continued after the first 24 hours.

Discussion

A review of 274 cases of lobar pneumonia treated with M. & B. 693 showed that with adequate dosage of the drug, the majority of cases may confidently be expected to respond within 48 hours of the beginning of treatment. An analysis of the 40 cases provisionally classified as 'indefinite or absent' response demonstrated that persistence of pyrexia beyond 48 hours, or relapse, need not indicate ineffectiveness of the drug, indeed, although the dose was considered inadequate in many cases, it was concluded that M. & B. 693 acted beneficially on the course of the disease in 23 cases, and may have prevented death in 5 other cases. The drug appeared to be ineffective in 17 cases (6 per cent of the total treated), but of these cases 4 received an inadequate initial dose (2 tablets, *t.d.s.*) ; 2 died within 36 hours of admission to hospital and one died of myocardial degeneration. Complications were conspicuously uncommon, delayed resolution occurred in 6 cases and in one case a staphylococcal empyema developed.

The importance of the following factors in influencing the response to treatment was also demonstrated :—

The response was less satisfactory in patients admitted after the 4th day of the disease, thus stressing the importance of early diagnosis and treatment. Age over 40 and severity of disease on admission adversely affected the mortality rate, but did not appear to affect the response to treatment in the other cases.

When toxæmia was sufficiently severe to cause death within a few hours after admission to hospital, treatment was not unexpectedly ineffective. In the present series one patient died within 10 hours and one within 36 hours, in

these cases death probably occurred before M. & B. 693 could exert its full therapeutic effect. Lack of realization by the coolie of the importance of early treatment will continue to swell the mortality figures of lobar pneumonia in spite of M. & B. 693 therapy. The remedy lies more in education of the public than in chemotherapy. On the Kolar Gold Fields most of the coolies are under strict supervision and daily inspection of the lines excludes the possibility of a sick coolie remaining in his quarters until his condition becomes hopeless (both patients who died soon after admission to hospital came from the surrounding villages). The introduction of M. & B. 693 soluble should improve the chances of recovery in moribund patients; all gravely ill patients should be given an initial dose of 3 c.c.m. (1 gm.) intramuscularly repeated if necessary at two or four-hourly intervals until the condition of the patient sufficiently improves to permit oral administration of the drug.

Intercurrent disease influenced the outcome in 2 patients, one succumbed to congestive cardiac failure secondary to myocardial degeneration and in one other fatal case diabetes and cardio-renal disease were contributory factors. It is equally important to note that 3 patients admitted with signs of congestive cardiac failure responded excellently to M. & B. 693. Severe intercurrent disease, especially myocardial and renal disease in elderly people, will continue to enhance the mortality rate in lobar pneumonia, but many of these cases can be saved by efficient M. & B. 693 therapy.

Faulty administration of M. & B. 693, either in quantity or spacing of doses, was undoubtedly the most important factor in poor or absent responses. This was well demonstrated by the higher proportion of less satisfactory responses in the 18 cases treated with initial doses of 2 tablets, *t.d.s.*; table VII shows that no case responded within 12 hours, and only 66.6 per cent responded within 48 hours compared with 86.7 per cent in the remaining 256 cases treated with higher initial doses.

The practitioner in some cases has to consider the expense of treatment, but the cure of disease should always come first and if a drug is indicated it should be given in effective doses. The strikingly satisfactory response of a few cases of lobar pneumonia to small doses of M. & B. 693 (such as 2 to 4 tablets daily) is very impressive,

but to expect all cases to respond in this manner is to court disaster. The dose of M. & B. 693 considered to be adequate has already been fully discussed, it is appreciated that 9 gm. during the first 24 hours is open to criticism as being too high for the average case and that many patients would respond to smaller doses, but unfortunately there are no criteria (apart from gravity of illness) to assist the practitioner in detecting the type of case requiring maximum dosage. An appreciable number of mildly or moderately ill patients will respond only to massive dosage. It is felt that the danger of under-dosage is greater than over-dosage and it is safer to give a dose which will be effective against the more resistant strains of pneumococcus. In this respect it is important to remember that in lobar pneumonia massive doses of M. & B. 693 rarely need be continued for more than 36 hours and usually the drug can be stopped in 48 to 72 hours. The possibility of severe drug toxicity is thereby minimized, clinical experience has shown that mild toxic symptoms are of little significance, but the danger of drug resistance following inadequate initial doses is a real one.

The analysis of the 'indefinite or absent' responses proves the necessity not only for an adequate initial dose but also for an adequate maintenance dose and four-hourly administration of the drug at all times. A secondary rise in temperature in certain cases (group 2) was probably due to the dose of M. & B. 693 being too rapidly reduced after the first 24 hours, and it is hoped that the administration of 2 tablets, *q.q.h.*, continued for about 8 hours after the temperature has fallen to normal will do much to eliminate these cases. It has been recommended that when the patient has been afebrile for 8 to 12 hours, in the majority of cases 1 tablet, *q.q.h.*, need only be continued for a further 24 hours, this period may be considered too short, but there does not appear to be any indication for routine prolongation of the administration. Premature withdrawal of the drug may give rise to a recrudescence of symptoms, and it is possible that the recurrence of toxæmia and pyrexia in certain cases in group 1 might have been due to this factor; all these cases, however, responded extremely well to increased doses of M. & B. 693, and it is concluded that as long as the patient is carefully observed there is little danger in this respect.

Type I pneumococcus appeared to be more resistant to M. & B. 693 than other types, this was not only a clinical impression but was also supported by the comparatively high incidence of type I pneumonia in the deaths (33.3 per cent). An investigation into the type of lobar pneumonia occurring on the Kolar Gold Fields has shown that about 15 per cent were due to type I, but as the investigation was not complete undue importance is not attached to

(Continued at foot of next column)

INCIDENCE OF LEAD POISONING AMONG HINDU WOMEN AND CHILDREN

By RAI BAHADUR K. N. BAGCHI, B.Sc., M.B., D.T.M., F.I.C., F.N.I.

Chemical Examiner to Government, Bengal, Calcutta

In connection with a series of investigations (under the Indian Research Fund Association) on the lead contents of human excreta, tissues and hair, it was discovered that hair of Hindu women, particularly of those who are married, is exceptionally rich in lead (*vide table I*) and the urine and faeces of some of the women whose

these figures and they are recorded without comment.

Summary

1. Two hundred and seventy-four cases of lobar pneumonia treated at the Kolar Gold Fields Hospital have been reviewed.
2. The mortality rate was 3.2 per cent.
3. The administration and adequate dosage of M. & B. 693 in lobar pneumonia have been discussed.
4. Forty cases (15.5 per cent) not responding to M. & B. 693 within 48 hours have been analysed with reference to causative factors.
5. The drug appeared to be ineffective in 17 cases (6 per cent) but in 6 of these cases other factors might have influenced the response to treatment.
6. The importance of adequate dosage has been emphasized as the most important factor in delayed or absent responses.

I wish to acknowledge my thanks to the managers of the Kolar Gold Fields, Messrs. John Taylor and Sons, 6, Queen Street Place, London, E.C.4, for their permission to publish this paper, and to the Chief Medical Officer, Dr. W. B. Roantree, for his valuable criticisms.

excreta of those who gave low lead figures in their hair (Bagchi *et al.*, 1940).

As these women, mostly belonging to the upper middle class, were not connected with any industry necessitating exposure to lead, an attempt was made to trace its source and the route by which it is introduced into the system. Candy (1933) states that the plating or 'tinning' of cooking and storing vessels with tin-lead alloys is the principal source of lead in cases of lead poisoning in India. Several samples of tin alloys which the tin-smiths use for tinning 'dekchis' (cooking utensils) were collected from different parts of Calcutta and examined, but none of them was found to contain an appreciable amount of lead. Similarly, the aluminium vessels and glazed surfaces, collected from cheap porcelain, earthenware and enamelled vessels, were examined and found to be practically free from lead. But these sources, even if they contained lead, could not possibly affect only the women and spare the men of the same family, for every one of them was exposed to the same extent to this risk. Attention was therefore directed to other sources which usually claim the exclusive attention of women, *viz.*, the scented hair oil, powder, creams and snows, vermillion, etc., and it was found that the vermillion used by married Hindu women was responsible for such state of things. Genuine vermillion, a more expensive stuff, is pure red sulphide of mercury imported exclusively from China and is known as 'China sindur' or Chinese vermillion, while the other brands of vermillion, some of them being scented for fashionable women and selling under various trade names, are nothing but red lead mixed with a red synthetic dye. Some of these dye-stuffs being powerful irritants damage the epithelium and produce roughness on the hair-parting where vermillion is applied.

It is known that lead is absorbed, though sparingly, through the unbroken skin and cases of lead poisoning have been known to follow the use of hair-dyes, lotions, cosmetics and grease paints containing lead. It has also been proved experimentally on laboratory animals by American workers (Kehoe and Thamann, 1931). The application of red lead to the scalp (anterior end of the hair-parting) by Hindu women is therefore a source of abnormal lead risk. The use of hair oil, which is common even amongst the poor, helps to hold the lead in contact with the scalp by forming lead soap with the fatty-acids of vegetable oils and thus favours absorption, especially if the epithelium of the scalp is damaged. Besides the absorption of lead by this route, there is also a probability of its absorption through the alimentary or the respiratory tract as well, on account of careless handling and unavoidable spilling of the substance at the time of its application. This is borne out by the fact that little children, specially the girls, living in close association with their mothers, imbibe an appreciable

amount of lead in their system (Bagchi *et al.*, 1940), although they do not use any vermillion (*vide table II*).

Since vermillion containing lead is used by a large proportion of Hindu women and since an

TABLE II

equally large number of children, who may be called 'contacts', are liable to imbibe lead through the other routes, incidence of lead poisoning is likely to be high among Hindu women and children but in actual practice no such cases are met with and so far no cases have been reported. This is perhaps due to the fact that by the expression 'lead poisoning', we always try to visualize the typical cases of plumbism with wrist-drop, anaemia, colic, obstinate constipation, blue line on the gums and other characteristic signs and symptoms, but which we never find. The apparent absence of lead poisoning may be accounted for by the following possibilities :—

(i) The dose of lead is perhaps too small and its absorption goes on *pari passu* with its elimination through the usual eliminatory channels including hair, (ii) the Hindu women and children are not susceptible to lead, or (iii) the signs and symptoms of chronic lead poisoning differ widely, under different conditions, from the classical signs and symptoms described in the textbooks.

It is believed that women are more susceptible to the action of lead, although this view is not shared by the German writers who consider that 'their poor state of nutrition, poverty and industrial fatigue added to house work, long hair and type of clothing favouring the accumulation of a greater quantity of the poison upon them' account for an 'apparent

increased susceptibility (Biondi, 1934). But all agree that in women, lead poisoning assumes a more severe form and menstrual disorders are very frequent (Biondi, *loc. cit.*). This is the state of things in European countries and amongst women who are directly connected with various lead industries, but the poor state of nutrition, poverty and few other conditions stated above may apply with greater force to Indian women, and they cannot possibly escape lead intoxication, however it is introduced into the system.

It has been proved that lead is absorbed in larger quantity and much more quickly through the lungs than through the skin, or the alimentary tract and produces the characteristic symptoms of poisoning. Even then, only few of the employees in lead works, where lead is likely to be introduced through the lungs, develop the symptoms, while others develop a relative immunity. The Hindu women expose themselves to the poisonous action of red lead for years together and some of them give definite proof of lead absorption as indicated by high lead-content of their urine and faeces (*vide table III*), but they never develop the textbook

TABLE III
Comparative statement showing the lead-content of urine and faeces (i) of healthy persons not exposed to lead, (ii) of women using vermillion and (iii) of men engaged in lead industries: mg. of Pb per kilo (Bagchi and Ganguly, 1937)

	Urine	Faeces	REMARKS
Group I. Healthy Hindus (not exposed to lead).	0.016	0.14	Only the maximum figures given.
Group II. Hindu women using vermillion:			
Case 1 ..	0.059	1.29	Suckling mother, quite healthy.
Case 2	1.05	Dyspeptic troubles and anaemia (a six-year old girl).
Case 3 ..	0.02	1.04	Abortions with negative W.R.
Case 4 ..	0.008	1.525	Dyspeptic troubles and mild alopecia.
Case 5 ..	0.08	0.88	Mild alopecia, otherwise healthy.
Group III. Compositors and solderers:			
Case 1 ..	0.06	2.4	Most of them suffering from lead poisoning with characteristic signs and symptoms of the textbooks.
Case 2 ..	0.124	1.05	
Case 3 ..	0.144	4.46	
Case 4 ..	0.364	2.28	
Case 5 ..	0.530	4.50	

symptoms. Bulky food, as taken by the average Indian, is known to interfere with absorption of lead ingested with food (Monier-Williams, 1938), therefore a portion of the vermillion that happens to be introduced into the gastro-intestinal tract is not completely absorbed through this route and does not furnish the extra doses of lead necessary to effect sufficient damage to the tissues for production of the characteristic symptoms. It has been stated (Porritt, 1931) that 'a slow, subtle, insidious saturation of the system by infinitesimal doses of lead extending over a long period of time produces a group of symptoms altogether different from the recognized forms of plumbism', while the massive doses of lead, as introduced mostly through the respiratory and alimentary tracts, produce the classical lead poisoning of the textbooks (compare groups II and III in table III). On the basis of the above statement we may reasonably expect that, if lead poisoning occurs at all, the insidious type may be the prevailing form among Hindu women and children.

Pathology and symptomatology of the insidious type

The signs and symptoms of the insidious type of poisoning are, in most cases, those of dyspepsia, such as loss of appetite, distaste for food, slight constipation, sometimes looseness of bowels with mucus (enteritis saturnina), flatulence, abdominal discomfort bearing no definite relation to food, and slight anaemia. In many cases arthralgic pains round various joints—the knees, elbows and shoulders being most frequently affected—are the only symptoms available (Price, 1929). In some cases arthritic pain with creaking or grating and impairment of movement and sometimes with slight swelling of a joint, may be present. Symptoms simulating gastric ulcer or malignant gastric disease with diarrhoea, vomiting and abdominal pain, but without haematemesis or melena have been recorded (Bramwell, 1931). Vertigo, headache and insomnia may also be the only symptoms (Price, *loc. cit.*). Lethargy, weariness of brain, sleepiness, disinclination for any effort with emotional outbursts, especially in women, mental confusion and 'bright girls becoming gloomy, taciturn and miserable' with no other indications for lead poisoning have been known to be the characteristic features in the insidious type of poisoning (Porritt, *loc. cit.*). Neurological manifestations, such as weakness of the extensors of the right hand, lower arm, the interosseous muscles and also of the shoulder muscles (Leschke, 1934), spastic paraplegia, anterior crural neuritis with anomalous symptoms, and a mild form of lead encephalopathy with symptoms of brain tumour (Bramwell, *loc. cit.*) have been recorded. A case of lead encephalopathy with mental confusion, paraplegia and paraesthesia was reported by Candy (*loc. cit.*). The man fell down unconscious on the road, and

remained so for 3 days. He made a rapid recovery under treatment for lead poisoning.

Menorrhagia and metrorrhagia have been known to be the principal signs in some cases. A married girl, mentally incoherent (duration one year) with slight spastic paraplegia and nystagmus (8 months), severe menorrhagia and metrorrhagia (4 months), and a history of abortion 2 years ago was successfully treated by Candy for lead poisoning. Frequent abortions and sterility are very common among lead workers. A woman who had previously given birth to three normal children, had nine miscarriages after her employment as a lead worker, and in a type-founding works half of the married women were sterile (Leschke, *loc. cit.*). Lead increases the incidence of eclampsia—the quantity of lead imbibed daily may be insignificant, but it may be enough to turn the scale and precipitate the occurrence of eclampsia in a pregnant woman on the verge of toxæmia (Porritt, *loc. cit.*). High maternal mortality is significant among women exposed to lead.

Lead damages the kidney, and interstitial nephritis with arterial disease is common in cases of lead poisoning; but nephralgia simulating passage of gravel through the urinary organs is not uncommon (Porritt, *loc. cit.*). High blood pressure is neither an essential sign nor an immediate consequence of lead poisoning. It is a complication arising only in small percentage of cases, probably owing to 'a special disposition of the blood vessels or damage to the centre for blood pressure in the mid-brain' (Leschke, *loc. cit.*). As cases of high blood pressure are occasionally noticed among Hindu women, the question of lead poisoning may be carefully considered. In many cases subnormal blood pressure (80 to 100 mg. of Hg.) has also been recorded.

Vascular spasm is an important effect of lead absorption and its manifestations may be noticed in various forms in different organs of the body. The vessels lose their dilatability and no longer dilate even with caffeine, nitrites, etc., but, paradoxically, are decreased in size by these drugs (Leschke, *loc. cit.*). No blood vessels escape the effects of lead. The splanchnic, renal, retinal, as well as the blood vessels of the brain, may be equally affected. These spasms are at first functional but may gradually bring about permanent pathological changes. The clinical signs of vascular spasm are manifested by slow hard pulse, increased blood pressure, contracted kidney, spastic constipation and pains in the abdomen varying from slight discomfort to violent colic. The spasm of the retinal vessels gives rise to transitory or even permanent blindness and that of the brain vessels causes an encephalopathy which may vary in intensity from simple mental incoherence, sleeplessness, headache or nervous exhaustion to epileptiform fits and unconsciousness. The coronary vessels are also affected and angina pectoris or heart cramps which develop as the result of a purely

functional coronary spasm may be the only symptom. It may, however, lead to permanent changes, such as sclerosis and thrombosis, observed in cases of the classical type of lead poisoning.

Chronicity of spasms in the blood vessels of the hair follicles of the scalp may cut off nourishment and thus give rise to *falling out of hair* which is a common complaint among Hindu women and may be a manifestation of the insidious type of poisoning.

Lead poisoning in children

If a mother suffering from lead poisoning suckles her baby, she is likely to transmit lead through her milk and set up a slow and progressive poisoning in the child (Biondi, *loc. cit.*). Lead affects children equally badly and in insidious cases only the gastro-intestinal symptoms may be present (Taylor and Schram, 1936). The relative immunity of children advanced by some authors is without any foundation. The children born of mothers suffering from plumbism are less healthy and frequently undersized and weakly, and are 'prone to be degenerate showing inacrocephaly, idiocy, imbecility and epilepsy' (Biondi, *loc. cit.*). Congenital debility in infants, marasmus, wasting, convulsions, obstinate constipation or enteritis with or without jaundice are frequently traced to lead intoxication and may be the cause of death of a large number of children (Milligan, 1931).

It may be contended that the use of red lead as vermillion is in vogue, in Bengal at least, for several decades past, but why it is incriminated now as the cause of so many ailments in women and children? The solution of this problem may be found in the researches of several workers on this subject. It has been experimentally proved that the type of diet exerts profound influence on absorption of lead. Milk, for example, retards its absorption considerably from the gastro-intestinal tract (Miyasaki, 1930). It was the principal article in the dietaries of the Hindus but poverty and expensive living in cities where people are migrating in large numbers, preclude its inclusion, in these days, even in the menus of children. This is one of the many important reasons to account for more absorption of lead leading to deterioration of health and development of the symptoms of poisoning.

Diagnosis and discussion

The physician cannot be blamed in any way for his inability to diagnose the insidious cases of lead poisoning as its possibility is not expected and never suggests itself. In some cases the physician may suspect lead as the cause of the clinical picture but a definite conclusion is difficult if the source of lead is not traced. The mistakes in the diagnosis of lead poisoning are often due to not expecting it (Bramwell, *loc. cit.*). In classical type of lead

poisoning with characteristic signs and symptoms, diagnosis is not difficult, but one should not expect to find punctate basophilia (stippled erythrocytes) in blood or the blue line on the gums, which are believed to be infallible signs of plumbism. In fact, the punctate cells have, so far, not been detected by competent pathologists in any of the typical cases of plumbism with wrist-drop, optic atrophy, violent colic, etc., among the compositors and solderers of Calcutta who were brought to my notice in connection with the administration of the Workmen's Compensation Act. The blue line may be an important and early sign on the pink gums of white people, but, on the dark or purple gums of an Indian, its identification is not easy, more so if the gums are stained with pan juice, tobacco preparations, *mishi* (astringent powder), etc. The blue lines or blotches are due to sulphide of lead, produced by the action of sulphuretted hydrogen, formed, as the result of putrefaction of food materials in the interdental spaces or around the teeth, on lead present in the gum tissue as an albuminate. It is, therefore, not found in people who are toothless or who take particular care of their teeth. Even in Europe, these signs are found only in a small percentage of cases. The type workers of Moscow developed the blue line only in 5.5 per cent and punctate basophilia in 13.3 per cent of the cases of lead poisoning (Leschke, *loc. cit.*). Harris (quoted by Biondi) could detect the basophilic cells only in 20 per cent of his cases. Kehoe (*loc. cit.*), on the other hand, states that the 'mere occurrence of stippled erythrocytes in the blood is not indicative of abnormal lead absorption and that the mere demonstration of stippling has no diagnostic value. The stippled erythrocytes are of frequent occurrence in the blood of persons who are apparently normal and healthy and who are free from abnormal lead absorption'. As this subject is still in a chaotic state, it is safer to ignore it altogether especially if the finding is negative.

In the insidious type of poisoning these signs are not to be expected. The other symptoms, already described, are often so ambiguous and simulate so many common ailments having no relation to lead, that the possibility of a correct diagnosis is always a remote one. Sir William Gowers (1893) stated, in connection with diagnosis of obscure cases of nervous diseases with anomalous symptoms, that 'it is not possible to avoid error in such cases except by the habit of remembering lead as a possible cause in obscure cases'. The dyspeptic symptoms which are often due to unbalanced diet, protozoal or helminthic infection of the gut, or some other tropical diseases, cannot be expected to be ascribed to lead if the physician does not know that his patient is exposed to an abnormal lead risk. The anaemia, abdominal discomfort, enteritis, constipation, etc., indicate so many diseases in the tropics that to remember lead as a possible cause for such ailments appears to

most of us to be a far fetched idea. Miscarriage and menstrual troubles are frequently attributed to specific infections, vitamin-E deficiency or to displacement of the uterus, even in the absence of a definite proof by blood test or by actual examination of the pelvic organs. As this country is industrially extremely backward, and as women, especially those belonging to the middle class and also those living in the countryside, have nothing to do with any industry, the question of occupational or industrial lead poisoning never arises and the physician would naturally think of all other conditions except plumbism.

The facts that women use vermillion and vermillion contains red lead should always be remembered. The obscure cases of anaemia with dyspeptic symptoms not yielding to treatment are so common, even amongst well-to-do Hindu women, both in cities and in the country, that a careful investigation about the aetiology of this condition with special reference to lead is called for. As some of these cases are associated with childbirth, the symptoms are likely to be explained under the clinical entity *sutika*, the aetiology of which is still obscure. The problem is further complicated by the 'selective action' of this element. Not only does it select a particular tissue or organ of the body (tissues most used and fatigued being affected early), but it shows a preference to a particular individual of the family (those with lowered resistance). Out of several women of the household using the same vermillion, only one or two are readily affected, while the others may escape altogether. This is explained in terms of idiosyncrasy, susceptibility or lowered resistance of the individuals thus affected. Different persons under the same conditions of lead exposure may show well marked variation in imbibing lead and producing symptoms of poisoning and the resistance of the same individual may also vary at different times (Monier-Williams, *loc. cit.*). A latent or dormant case of poisoning with an apparently good health record may become a pronounced case after starvation, medication, shock, acute infections, disturbance of calcium metabolism, changes in diet, etc. (Lynch *et al.*, 1934). The above conditions bring about 'mobilization' of lead from the bones which form 'lead depots' in our system and possibly from the reticulo-endothelial system which is known to retain a large quantity of lead. The mobilization is also effected during treatment of plumbism by certain de-leading agents, such as potassium iodide and sodium bicarbonate, which produce soluble salts of lead from insoluble lead phosphate in which form it is locked up in the bones. One should, therefore, be careful in prescribing these drugs in cases of lead poisoning.

Chemical examination of urine and faeces for determination of their lead-content is an important aid to detection of abnormal absorption of lead, and possibly to diagnosis of lead

poisoning. The latest methods of analysis give accurate figures of lead in all biological materials, and normal lead-content of human tissues and excretions have thus been carefully worked out (*vide tables IV and V*). These results have upset many of our preconceived

TABLE IV

Lead in normal urine and faeces : mg. of Pb per kilo (Bagchi and Ganguly, 1937).

ideas of lead poisoning and of lead in the tissues and excretions. Nowadays, the mere detection of lead in the urine, which was considered sufficient for purposes of diagnosis only a few years ago, is not regarded as of any diagnostic value. Any excess of lead over the normal limit either in the urine or in faeces indicates high absorption from abnormal exposure to lead and high absorption may or may not mean lead poisoning—the clinical picture and a sound clinical judgment of the physician being the determining factors.

The amount of lead present in the urine is not always a reliable guide to form a definite

opinion. It shows wide variability and sometimes appears to be misleading. In some cases, it is persistently low (within the normal range), although the faecal lead gives definitely high figures. The urinary lead excretion does not increase proportionally with increased lead exposure beyond a certain point (Kehoe *et al.*, 1933) and this point, the threshold value, so to say, appears to vary widely in different individuals. The faecal lead excretion is, on the other hand, an important guide for determining the lead absorption. It has been experimentally proved by several workers that a considerable portion of the lead in the system is eliminated through the faeces and only a small fraction is left for the kidneys to eliminate through the urine. The faeces contains (1) unabsorbed lead normally present in food, (2) unabsorbed extraneous lead ingested with food, (3) lead absorbed from the alimentary tract and excreted again into this tract for elimination, and (4) lead introduced into the general circulation through routes other than the gastrointestinal and mostly excreted by way of the liver and bile. It is therefore evident that the faecal lead indicates the actual state of lead exposure and absorption (*vide table III*). The chemical examination of blood does not help in any way in cases of insidious type of poisoning. The lead figure is always low (within the normal range) in these cases.

Lead workers always imbibe a large quantity of lead and consequently excrete, especially through the faeces, much higher amounts than what we find in the excreta of men with ordinary lead exposure. But only a few of these workers develop poisoning and the rest enjoy an apparently good health, although both these groups show high lead absorption. Case 1 in group II (table III) gave higher lead figures in her urine and faeces, but she had no complaints whatever, while the cases 2 and 3, having much less lead in their excreta, gave indications of lead intoxication. If a woman with excess of lead in her excretions, as for instance case 1, falls a victim to dyspepsia, due to causes not related to lead, or if she acquires a colic due to gall-stones, urinary calculi, appendicitis or gastric ulcer, or if she develops anaemia with weakness, lethargy and loss of weight due to commencing tuberculosis, the diagnosis becomes exceedingly difficult. The laboratory findings only remind the physician of the possibility of lead poisoning and do not help him otherwise. The physician at the same time must not forget that 'one can have fleas and lice together'.

Sale of vermillion is a public health question

The manufacture and sale of vermillion may be considered as an important public health problem and perhaps more important than the sale of adulterated food or drugs. There is no doubt that Hindu women and children, especially in Bengal, are exposed to an abnormal lead risk

which is peculiar in so far as it is neither accidental nor occupational. The subtle action of lead producing anomalous symptoms escapes the notice of the physician and it is difficult to establish the diagnosis of the insidious type of poisoning in this country. It is obviously a danger from an entirely unexpected quarter and as it is associated with time-honoured custom which is almost a religious institution with Hindu women, it is not possible to interfere with the use of vermillion in any way. The difficulty of stopping the manufacture and sale of adulterated vermillion can only be overcome if the State comes to the rescue. The health of the middle-class people is far from satisfactory and it is rare to find, in these days, women and children who are free from the so-called 'liver and dyspeptic troubles'. As lead is one of the causes of such troubles the problem of supplying genuine vermillion (free from lead) deserves careful consideration of Government and the public alike and necessary steps should be taken to stop the sale of adulterated vermillion.

Summary

Lead poisoning of industrial or occupational origin is unknown among women in this country. Men employed in printing presses, type-foundries, etc., frequently suffer from lead poisoning.

In connection with investigations on the lead-content of normal human tissues, excreta and hair, it was discovered that hair of Hindu women is very rich in lead. The source of lead was traced to cheap vermillion which contains red lead mixed with a red synthetic dye. That lead is absorbed through the scalp where it is applied, is indicated by high lead figures of the urine and faeces of these women.

The slow and steady absorption of lead extending over a long period may produce either the classical type or the insidious type of lead poisoning. Among Hindu women the classical type of poisoning is unknown. It has been suggested in this paper that some common ailments, such as anaemia, menstrual troubles, frequent abortions, dyspepsia, nervous troubles, high blood pressure, weariness of brain and body, etc., which are frequently met with among Hindu women, especially in Bengal, may be due to the insidious type of lead poisoning. Frequent abortions and sterility in women may, in the absence of other causes, be due to lead.

The diagnosis of such cases of lead poisoning is exceedingly difficult. The chemical examination of the urine and faeces is useful as an aid to diagnosis, but these findings as well as the objective symptoms, such as punctate basophilic (which is seldom found in Indian blood) and blue line on the gums, indicate only lead absorption and not necessarily lead poisoning. Lead absorption and lead poisoning should be clearly differentiated. In the insidious type of

CHEMOTHERAPY IN PLAGUE

(From the Haffkine Institute, Bombay)

WHILE the experiments described by Sokhey and Dikshit (1940) on the action of sulphathiazole in experimental plague infection in mice were being carried out at the Haffkine Institute, a research unit from the Institute was conducting at Bettiah, Bihar, a field trial on the therapeutic value of the Haffkine Institute anti-plague serum. Advantage was taken of this circumstance to test the therapeutic action of sulphapyridine (M.&B. 693) and sulphathiazole

(Continued from previous column)

poisoning, the lead-content of blood is within the normal range.

For differential diagnosis, the greatest difficulties may be given by those women suffering from gall-stone or urinary colic, appendicular troubles, early tuberculosis, or dyspepsia due to errors in diet, and at the same time giving high lead figures in their urine and faeces due to red lead being absorbed through the scalp.

Legislation to prevent the adulteration of vermillion with red lead has been suggested.

in human plague infection also. Because of our unfamiliarity with these new drugs in the treatment of plague, we worked with a comparatively small dosage. In spite of this handicap the trial has yielded very important indications for the treatment of plague and we give the results in this paper.

Material and methods

At Bettiah, Bihar, plague broke out in epidemic form at about the end of last year. Bettiah Raj erected a temporary hospital with 30 beds for the treatment of plague cases and a medical unit was sent out from the Haffkine Institute to undertake the treatment. The unit commenced work early in January 1940 and was there till the first week of May. During this period, 294 cases in all were admitted for treatment. No selection of cases was made but patients as they were admitted were taken up in rotation for different forms of treatment. Thus, the first patient to be admitted received antiplague serum, the second admission received the usual hospital treatment, i.e., iodine solution intravenously and served as a control, the third admission received sulphapyridine, fourth again received antiplague serum, the fifth iodine control, sixth sulphapyridine and so on until admission no. 207. Thereafter, sulphapyridine was replaced by sulphathiazole. Later, it was decided to treat a larger number of patients with sulphathiazole. With this object in view treatment with serum was stopped and from admission no. 246, each alternate admission was treated with sulphathiazole, the other admissions serving as controls. From admission no. 262 two consecutive admissions received treatment with sulphathiazole and the third admission was used as control and treated with iodine.

On admission every patient was carefully examined for a bubo and other clinical signs of plague; 0.5 c.cm. of his blood was drawn from a vein and was spread in two equal portions on two agar slopes, in order to detect the presence of septicæmia and its degree if present. Immediately after this the patient was put on the specific treatment. Later, if the blood culture proved to be negative, the bubo was punctured with a needle and sucked-up material put up for culture. Out of 294 admissions, 19 proved not to be cases of plague. In addition to these 19 cases the following other cases require to be excluded. Six patients received combined treatment with serum and sulphapyridine—the number of cases so treated was too small to throw any light on the combined treatment; 4 patients left hospital before treatment was completed; 11 patients who were moribund at the time of admission died soon after (within 12 hours); 11 patients for whom blood cultures were not done for one reason or another could not be classified; and 6 patients proved to be cases of primary pneumonic plague; these are discussed below separately. Thus, it left 237 cases of bubonic plague which are accounted for in tables I and II.

Treatment

Antiplague serum (Haffkine Institute).—Forty e.c.m. of the serum was given on the day of admission—20 c.cm. intravenously immediately on admission, and 20 c.cm. subcutaneously 6 hours later. The same quantity of serum was given the next day in a like manner. Subsequent dosage and duration of treatment depended on the severity of the case. Mild cases did not require any serum after the first 2 days, while for severe cases it was administered usually for 5 days. The following precautions were taken for the intravenous administration of the serum :—

(1) The serum was warmed to body temperature, and diluted with double the quantity of similarly warmed 25 per cent glucose saline.

(2) The serum-glucose-saline mixture was given slowly so that the 20 c.cm. of serum took at least 20 minutes to administer.

(3) 0.5 c.cm. of adrenalin chloride solution (1 : 1,000) and 1/100th grain of atropin sulphate were injected subcutaneously as a routine just before the first intravenous injection. During subsequent intravenous injections they were given only when required to treat the serum-shock.

In spite of these precautions, approximately 15 per cent of the cases treated with serum developed serum-shock either during the first or subsequent injections. These shocks, though sometimes alarming, were amenable to adrenalin and did not adversely affect the final result.

Sulphapyridine.—Two tablets (each 0.5 g.) were given on admission and one tablet every 4 hours thereafter for a maximum period of 7 days. The administration of the drug was however stopped earlier if the temperature of the patient came to normal and there was a distinct improvement in his general condition. To comatose patients the drug was given intramuscularly or intravenously and for this purpose the soluble salt was used, the dosage employed being the same as in the oral route. The same mode of administration was adopted when oral administration of the drug produced persistent vomiting. Such cases requiring parenteral administration of the drug were however rare. Another toxic symptom noted was that 4 out of 58 cases treated developed a spasmodic abdominal pain around the umbilicus after about 12 g. of the drug had been given. One case developed a combined urticarial and erythematous rash on the trunk and the extremities after receiving 4 g. of the drug. This rash disappeared of itself later.

Sulphathiazole.—This drug was given in the same dosage as sulphapyridine. The soluble sodium salt was given intramuscularly when the drug could not be given by the mouth. In general the same toxic symptoms were observed as with sulphapyridine, except they were on the whole of a milder character.

Iodine.—The controls received the usual hospital treatment in vogue for cases of plague in

India, i.e., iodine solution intravenously. For this purpose a stock solution containing 5.5 g. of iodine and 8.5 g. of potassium iodide in 100 c.cm. of distilled water was prepared. 0.5 c.cm. of this solution diluted with 10 c.cm. of distilled water was given intravenously. The same dose was repeated every day for 5 days. The treatment was stopped earlier if the temperature came down to normal and the general condition improved.

Results

We have presented the results in the following two tables. Table I incorporates the results of treatment in all the 237 cases with bacteriologically confirmed diagnosis of plague without making any differentiation into septicaemic or non-septicaemic cases. Presence or absence of septicaemia at the commencement of treatment

TABLE I
All cases of bubonic plague treated

Treatment	Number of cases	Number of deaths	Case mortality, per cent
Antiplague serum	70	20	28.5
Sulphapyridine (M.&B. 693)	53	13	24.5
Sulphathiazole	32	5	15.6
Controls—treated with iodine solution intravenously.	82	43	52.4
TOTAL ..	237	81	..

is however a very important factor, and, in our opinion, the chief factor which decides the issue. In our experience, if the infection remained localized in the lymph glands spontaneous recoveries invariably occurred, but, if the organisms broke through the lymphatic barrier and invaded the blood stream, death invariably resulted. As we had examined the blood of 237 patients immediately on admission we were in a position to know whether they had septicaemia at the commencement of treatment and the results of treatment in such septicaemic cases are given in table II.

TABLE II
Cases with plague septicaemia at the commencement of treatment

Treatment	Number of cases	Number of deaths	Case mortality, per cent
Antiplague serum	33	20	60.6
Sulphapyridine (M.&B. 693)	30	13	43.3
Sulphathiazole	12	5	41.7
Controls—treated with iodine solution intravenously.	40	38	95.0
TOTAL ..	115	76	..

Cases of pneumonic plague

During the course of this field investigation 6 patients suffering from primary pneumonic plague were admitted to the hospital. They all came from the same household, 4 were admitted on one day and the other 2 the next day. Two patients were treated with iodine solution given intravenously and served as controls; the other 4 received sulphathiazole. It is almost certain that patients were brought to the hospital soon after the onset of the disease. On admission, sputum of all the patients showed very large numbers of plague bacilli and cultures of blood all proved sterile. In the case of the 2 control cases, i.e., treated with iodine, plague bacilli appeared in blood about 24 hours after admission and both patients died on the third day. Duration of life after admission was less than 3 days. The 4 cases treated with sulphathiazole received approximately 4 g. of the drug daily. Two patients died on the third day, third patient on the fourth day and the fourth patient on the 11th day after admission. The characteristic feature of the cases treated with sulphathiazole was that daily cultures from the blood remained sterile in all cases, even in the case of the patient who lived for 11 days. No buboes developed in any of these patients at any time. In our numerous field investigations this is the first time we have come across cases of pneumonic plague. We shall discuss this more fully elsewhere. In these cases also we feel we did not give enough of the drug.

Discussion

Table I shows that in all cases of plague taken together, i.e., including both septicaemic and non-septicaemic, nearly 50 per cent died of the infection when treated with iodine. We have taken these cases as controls and propose to judge the effect of chemotherapy against these controls. It must, however, be remembered that iodine is claimed to have at least some curative action in plague, and, therefore, if the control cases had received only a symptomatic treatment and no iodine, the curative value of the serum and the two drugs would perhaps have appeared still better. However, as will be seen from the table all the three curative agents employed, viz, the serum, sulphapyridine, and sulphathiazole produced a significant reduction in the case mortality, the percentage of deaths being 28, 24 and 15, respectively. The different percentage mortality rates obtained with the different forms of treatment is probably due to the unequal number of cases treated.

Statistically there does not appear to be any significant difference between the results of the three treatments. It may also be stated here that the unclassified and moribund cases left out of consideration, as noted above, were so evenly distributed that even if they are included they make no significant difference in the results.

The curative value of these chemotherapeutic agents under very severe conditions is however seen from table II, which records results obtained in septicæmic cases. Plague septicæmia is a very serious condition indeed, as the control cases, of which nearly 95 per cent died, show. In septicæmic cases treated with sulphathiazole and sulphapyridine, however, the case-mortality was reduced to about 40 per cent, i.e., more than half of the cases treated recovered. Similar but slightly inferior results were obtained with the antiplague serum. This difference again may be due to unequal number of cases treated. Statistically no significant difference is apparent.

As regards the serum, we experienced serious difficulties in its administration. We wanted to give large dose but intravenous administration of even 20 c.cm. of the serum produced alarming symptoms in quite a number of cases. In our experiments with antiplague serum, it was found necessary to inject 0.4 c.cm. of the serum for a mouse of 25 g. weight. By analogy the equivalent dose for man weighing about 120 lb. would theoretically be in the neighbourhood of one litre and, even after allowing for the marked difference in the susceptibility to plague infection for the two species, a much larger dose than 200 c.cm., the maximum we used, would be needed.

It is now well recognized that, in the treatment with the sulphanilamides, it is the effective level of blood concentration of the drugs that decides the therapeutic result. This effective level varies with the nature of the infection, the degree of infection, and the animal to be treated. The defence mechanisms of the body are better developed in some animals than in others and it is generally conceded that these defence mechanisms co-operate with the chemotherapeutic agents in finally overcoming the infection. In the treatment of experimental plague infection in mice reported by Sokhey and Dikshit (*loc. cit.*), the best results were achieved with a concentration of free sulphathiazole in blood varying between 20 mg. and 10 mg. per 100 c.cm. (unreported figures). This concentration was maintained with an oral dose of 20 mg. given twice a day for 10 days for mice with an average weight of 25 g. In the case of the treatment of human cases reported in this paper, no effort was made to determine the level of the drug in blood reached, because we lacked the necessary facilities. But there is reason to believe that with the dosage of sulphathiazole and sulphapyridine used (about 3 g. a day), a concentration in blood of about 2 to 3 mg. per cent of the drug only could have been reached. Plague infection is much severer in mice than in men; 100 per cent of the mice infected with our standard infective dose die, while human case mortality in various epidemics varies between 50 and 80 per cent. In spite of this difference, a concentration higher than 2 to 3 mg.

A NOTE ON DRIED BLOOD PLASMA AND ITS PREPARATION IN INDIA

By S. N. HAYES, F.R.C.S., F.R.C.O.G.

LIEUTENANT-COLONEL, I.M.S.

Professor of Obstetrics and Gynaecology, King Edward Medical College, Lahore

J. N. RAY, D.Sc., Ph.D., F.I.C.
Director, University Chemical Laboratories, Lahore.

and

N. N. CHOPRA, M.Sc., A.I.C.
Research Scholar, University Chemical Laboratories, Lahore

THE difficulties associated with blood transfusions in this country are many, the chief being that associated with the production of a donor of the correct group at the requisite time. Blood banks may overcome certain difficulties, but are wasteful in that stored blood occupies a large

(Continued from previous column)

per cent is clearly indicated and we believe that with higher concentrations, results much superior to those obtained in the present series will be achieved. We propose to try this out in the field trials under way at present.

Summary

1. A report of treatment of 237 cases of plague with the Haffkine Institute antiplague serum, sulphapyridine and sulphathiazole in an epidemic at Bettiah is given.

2. In all cases taken together without differentiation into septicæmic or non-septicæmic cases, the case mortality in the serum, sulphapyridine, and sulphathiazole treatment was 28 per cent, 24 per cent and 15 per cent, respectively, as against 52 per cent in the controls. These reductions in case mortality are statistically significant, but not so the differences in the results of these different treatments.

3. Even in those severe cases in which septicæmia was present at the commencement of treatment all the three forms of treatment reduced the case mortality from 95 per cent in the controls to about 50 per cent in treated cases.

4. Six cases of primary pneumonic plague are reported.

5. The question of dosage employed has been discussed and it is suggested that a larger dose especially of the sulphanilamides used would reduce the case mortality still further.

Our thanks are due to Messrs. May and Baker for putting a liberal supply of sulphapyridine (M.&B. 693) at our disposal. Sulphathiazole was prepared in the Haffkine Institute and the powder was made into tablets by Cipla Laboratories, Bombay, to whom also our thanks are due.

amount of refrigerator space and only keeps for 30 days. They are only practicable in large towns. Recent work on the use of blood plasma (and serum) has altered the entire outlook of the treatment of shock and haemorrhage.

Cannon, Fraser and Hooper (1919) showed that in shock there was a diminished blood volume and haemo-concentration. Blalock (1931) pointed out that in experimental burns there was a loss of whole plasma from the circulation. Walther (1937) confirmed this and pointed out that the rational treatment was to supply plasma to the denuded circulation. It is clear that shock is associated with the loss of plasma from the capillaries producing a concentration of blood cells.

Walther's contention has been proved by all recent workers and the present method of election in the treatment of shock is by transfusion with plasma (or serum), the essential constituents being the blood proteins.

Best and Solandt (1940) have shown that both plasma and serum are equally efficacious. In haemorrhage the obvious method of treatment is to replace the blood lost by blood of a suitable type and until recently this has been the method in use. Recent work however has emphasized the value of plasma and serum. In practice, haemorrhage without shock is extremely rare. Edwards, Kay and Davie (1940) point out that it is very rare for a patient to lose more than three pints of blood in a severe haemorrhage, as the resulting lowering of blood pressure causes cessation of the bleeding. In such cases, a patient is left with 75 per cent of the erythrocytes in some part of the circulation. Providing therefore that the blood pressure can be raised and maintained by the introduction of a fluid of a suitable osmotic pressure into the circulation, a three-pint loss of blood can be treated and favourable results expected. Plasma or serum provide such a fluid.

As haemorrhage rarely occurs without shock and the accurate separation and estimation of either of these conditions are extremely difficult, it is more than probable that the cause of death in haemorrhage cases is due to a combination of blood loss *plus* shock. One factor common to both is loss of blood proteins contained in the plasma. The obvious method of treatment is to restore and maintain the circulatory volume by the administration of the proteins. This can be done by transfusing with plasma or serum.

In earlier work, liquid plasma or serum were used and has the advantage that a certain amount could be given without reference to blood grouping. They were stable at room temperature. Blood plasma and serum can be solidified and in the west have been kept at room temperatures for 12 months without

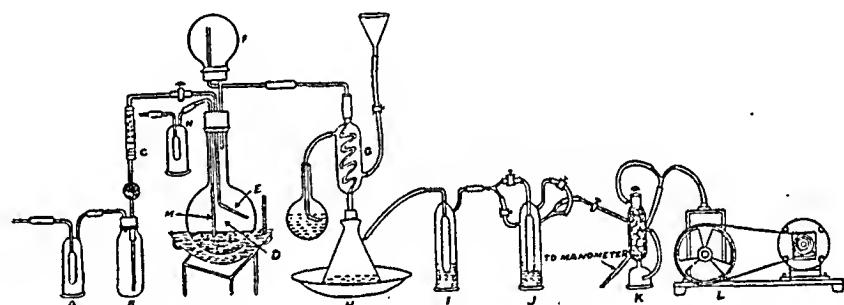

deterioration and with a considerable saving of storage space.

It appears that in solid plasma and serum we have substances for the treatment of shock and the majority of haemorrhage cases possessing none of the disadvantage of whole blood transfusion and which should be of the greatest value in this country in that a valuable method of treatment is made easily available for outlying towns. Its use in the field during war is obvious.

The requirements for a transfusion are 20 grammes solid plasma dissolved in 250 c.cm. distilled water which is the equivalent of the plasma-protein value of one pint of citrated blood. Up to 500 c.cm. can be given regardless of blood grouping. Twenty grammes plasma fills an ordinary-sized test-tube.

Method of preparation

For converting liquid plasma into a crystalline solid, we have modified the procedure of Edwards, Kay and Davie (*loc. cit.*) and have employed an apparatus whose sketch is here reproduced:—

A is a bubbler containing 0.1 per cent mercuric chloride solution to sterilize the incoming air.

B is the liquid plasma bottle. This bottle has a screw top and a metallic screw cap with two small holes and with a rubber diaphragm through which liquid plasma can be introduced by means of a needle.

C is an arrangement of a bulb containing sterile gauze and a tower containing glass beads or short bits of thin glass tube for filtering the plasma.

D is the actual drying flask into which the plasma is introduced in the form of a strong thin jet or spray through the tube E which is drawn to a fine point.

F is a safety flask used to collect any froth which flows back into the flask D. The flask D is heated in a thermostat maintained at 37°C. The water vapours are condensed at G and collect in the receiver flask H which is surrounded with ice. By maintaining a flow of ice cold water through the condenser G and by keeping the receiver H also ice cold, the speed of distillation has been increased. The flask H is connected to the bubbler I containing 0.1 per cent mercuric chloride solution which eliminates all chances of infection if there is a back diffusion. The bubbler I is connected with the bubbler J in such a way that J can be put in or out of the circuit at will without interrupting the vacuum. A soda lime tower R is interposed between the whole apparatus and the vacuum pump L. Before starting, the entire apparatus from B to H is sterilized with a dummy empty bottle at B which is then replaced by a fresh bottle containing the liquid plasma, and the distillation is started and continued till all the available plasma has been dried. The flask D is provided with another inlet tube M to

SEDIMENTATION RATE OF RED BLOOD CELLS IN EPIDEMIC DROPSY

By C. L. PASRICHA

MAJOR, I.M.S.

K. S. MALIK

and

S. LAL

(From the Epidemic Dropsy Enquiry, Indian Research Fund Association, School of Tropical Medicine, Calcutta)

THE sedimentation rate of the red blood cells was determined of 74 epidemic dropsy patients and of 8 persons in whom symptoms resembling those of epidemic dropsy were produced after taking food cooked in mustard oil incriminated in natural outbreaks of the disease or in mustard

(Continued from previous page)

drive off vapours whenever desired. M is provided with another mercuric chloride bubbler N.

After drying, the mass of solid plasma is removed aseptically and packed in convenient-sized tubes after grinding. Edwards *et al.* (*loc. cit.*) recommend that the dried plasma should be ground into a fine powder to facilitate solution in distilled water, or 5 per cent glucose solution. Our experience however is that it is best to grind it only to the stage when it will pass through a sieve, approximately no. 12. Contrary to the above authors we find that finely-powdered plasma takes much longer to dissolve than the coarsely-powdered one, on account of the difficulty of wetting with the former. Coarsely-powdered plasma dissolves rapidly and entirely. Often, however, there remains a very slight undissolved residue. This residue is probably denatured fibrin or some other protein and rarely amounts to more than 0.1 to 0.5 per cent of the total dry plasma. This minute residue can be filtered through a Seitz, Berkfeld or Chamberland type of filter.

All published work up to the present has been undertaken in a temperate climate and nothing as yet is known as to the effects of variable conditions found in the tropics on plasma and serum. We are undertaking investigations into these questions, and other biochemical and clinical aspects of dried plasma production, properties and therapy. Results will be published in due course.

Acknowledgments

We wish to express our thanks to Doctors A. Sami and S. R. Dhall and Mr. A. A. Qureshi for their assistance.

oil to which known quantities of argemone oil had been added (Chopra *et al.*, 1939). The cell volume and the haemoglobin percentage were also estimated. The methods employed were :—

1. *Sedimentation rate.*—Westergren's (1926) method was used. The readings were taken every 10 minutes for 2 hours. The tests were carried out at room temperature which varied from 29°C. to 34°C. during the period of these examinations. Although from observations made on parallel tests carried out at different temperatures, there is an acceleration in the rate of sedimentation at higher temperatures, the actual difference within the range of room temperature 29°C. to 34°C. is not sufficiently great to alter materially the results obtained.

2. The cell volume was determined by noting the volume of packed cells after centrifugalization at 3,500 revolutions for half an hour. The anticoagulant used was a mixture of potassium oxalate and ammonium oxalate in proportions recommended by Wintrobe and Landsberg (1935). The tubes after the addition of the solution of anticoagulant were dried over calcium chloride under vacuum in a desiccator.

3. The haemoglobin was estimated according to Newcomer's method using the Klett-Newcomer's glass standard equivalent to 0.038 per cent haemoglobin solution. The 100 per cent haemoglobin by this method is equivalent to 15.3 grammes haemoglobin per 100 c.cm. of blood.

4. The corrections of the sedimentation rate were made according to Wintrobe and Landsberg's (1935) graph in which corrections are made for variations in the cell volume. The average cell volume was taken as 43 instead of 47 used by Wintrobe and Landsberg.

As a control the blood sedimentation rate was estimated of 22 apparently healthy adults of the labouring class between the ages of 25 to 40. Individuals belonging to the labouring class were selected as the epidemic dropsy cases examined were mostly of that class. The results are given in table I.

The cell volume in this series of apparently healthy individuals ranged from 36.0 to 49.8 with an average of 43.1 and the haemoglobin between 13.4 to 18.1 grammes per 100 c.cm. of blood with an average of 15.3 grammes.

A summary of the results of the sedimentation rate, the cell volume and the haemoglobin content of 74 patients suffering from epidemic dropsy is given in table II. At the time of examination the patients were suffering from active disease and the degree of oedema is taken as an index of the clinical condition.

The increase in sedimentation rate is most marked in patients during the acute stage of the disease and is less in patients with slight or no oedema. The decrease in haemoglobin content is most marked during the acute stage of the disease. The cell volume is also decreased during the acute stage.

The results of examinations carried out in six patients during the acute stage of the disease and again when symptoms had subsided are given in table III.

The results show that with a cell volume above 35 and haemoglobin above 12.6 gramme per 100 c.cm. or 82 per cent haemoglobin oedema was not often present or when present was only slight. This is well seen in tables IV and V.

The blood sedimentation rates of eight individuals who ate food cooked in mustard oil containing approximately 5 per cent of argemone

oil and who subsequently developed symptoms resembling epidemic dropsy are given in table VI.

The first two cases had marked acceleration of sedimentation rate with low cell volume and low haemoglobin. These two individuals were the worst sufferers. The third, fourth and fifth cases were not markedly ill when the blood was examined but became worse a few days later. The last three cases had transient oedema and recovered rapidly. These results illustrate the value in prognosis of the blood sedimentation

rate, a marked increase in sedimentation rate indicates a bad prognosis. There were however certain anomalous cases. A patient with moderate degree of oedema and who recovered rapidly had blood sedimentation rate of 150 mm. (uncorrected) in 1 hour and two patients with well-marked oedema and in whom recovery was slow had sedimentation rates of 30 and 32 mm. in 1 hour.

In view of the generally accepted opinion that fibrinogen plays a large part in determining the rate of sedimentation of human red blood cells, estimations were made of the sedimentation rate, the cell volume, the haemoglobin and the fibrin-

The sedimentation rate, the cell volume and the haemoglobin content of eight individuals who ate food cooked in mustard oil containing 5 per cent argemone oil and who subsequently developed symptoms resembling epidemic dropsy. The estimations were made within a week of the onset of symptoms

Serial number	Sedimentation (mm.) after 1 hour	Cell volume	Hæmoglobin, grammes per cent
1	123	28.6	9.5
2	104	31.5	10.5
3	91	38.3	12.8
4	71	41.9	15.8
5	65	35.5	11.8
6	41	39.3	13.7
7	39	41.5	14.5
8	33	34.3	11.3

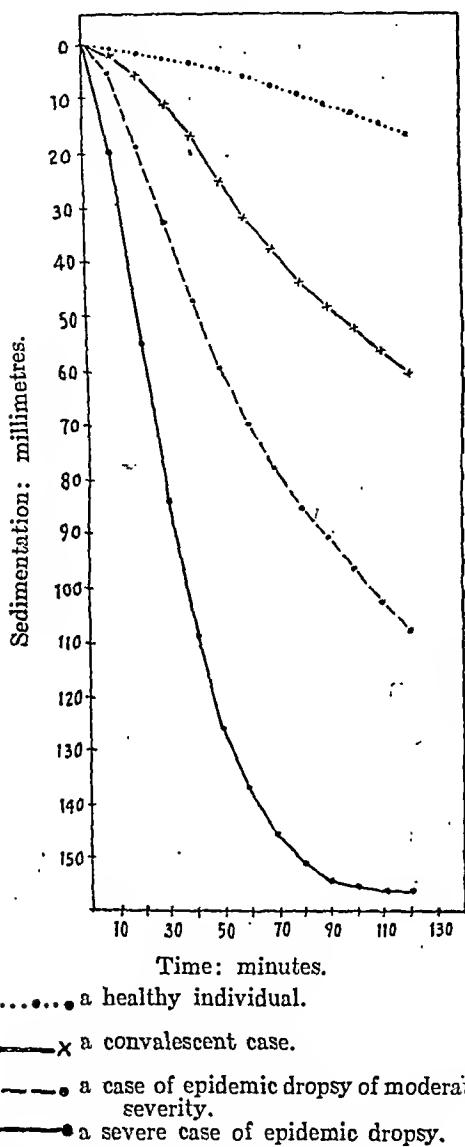

nitrogen content of 20 cases of epidemic dropsy. The results obtained suggest that the sedimentation rate, the fibrin content and the cell volume are interrelated. An increase of fibrin leads to an increase of sedimentation rate provided the cell volume is the same. An increase of cell volume decreases the sedimentation rate provided the fibrin content is constant.

The blood sedimentation rate was estimated every 10 minutes for 2 hours. In the graph are given representative results of the readings taken in (1) a healthy individual, (2) a convalescent case, (3) a case of epidemic dropsy of moderate severity and (4) a severe case of epidemic dropsy. The results, which are typical examples taken from a number of observations, show the increase in the sedimentation rate during the acute stage and the return towards normal during convalescence. The sedimentation rate serves as an index of the severity of the outbreak.

Recent work on the sedimentation rate of red blood cells has shown that this non-specific test is a valuable index in indicating disease processes where other tests often fail. An outbreak of epidemic dropsy in a closed community in which 242 boys had been exposed to the same

risk was studied recently. Nine boys who were in apparently good health and had no symptoms or signs suggestive of epidemic dropsy were found to have increased blood sedimentation rate. The average blood sedimentation in these nine boys was 55 mm. with limits of 19 to 122 mm. in one hour. There was a definite increase of sedimentation rate of the red blood cells thus

GRAPH

suggesting that these boys were in a pre-epidemic dropsy state. The use of mustard oil for cooking purposes was stopped and the outbreak of epidemic dropsy came to an end and it was not possible to investigate this point further.

Summary

The sedimentation rate of red blood cells, the cell volume and the haemoglobin content were estimated in a series of 74 cases of the natural disease and in 8 persons in whom symptoms resembling those of epidemic dropsy were produced following the intake of mustard oil containing argemone oil.

BIOLOGICAL CONTROL OF CULICINE MOSQUITOES, BY PRAWNS IN A BENGAL COAL MINE

By FRANK McCAY, M.A., M.D. (Cantab.),

D.T.M. & H. (Lond.)

Chief Medical Officer

and

R. SENIOR WHITE, F.R.S. (Edin.)

Malariaologist, Bird and Co., and to the Bengal Nagpur Railway

In January 1939 Culicine mosquitoes were discovered breeding prolifically in the small shallow pools that had accumulated near the wet working 'face' in some of the galleries of a section of Saltore colliery. This mine is about 130 miles away from Calcutta and three miles to the west of the Grand Trunk road and lies for its greater part under the junction of the Damodar and Burakur rivers where they form the north-western boundary of Bengal. The mosquitoes were probably sucked into the mine in the main air draught and then either flew or were blown along the galleries which here were about 1,000 feet underground. Conditions were ideal for breeding as the temperature remained constantly at about 90°F. and the humidity at 80 per cent all the year round; there was, moreover, a plentiful supply of human blood available

(Continued from previous column)

The sedimentation rate of red blood cells is increased in epidemic dropsy and this test is useful in excluding non-epidemic dropsy cases and in prognosis. There was not a single case of established epidemic dropsy in which the sedimentation rate was not increased. As a rule, the higher the rate, the severer the disease and the worse the prognosis.

In an outbreak of epidemic dropsy in a closed community evidence was obtained suggesting that the increase in sedimentation rate occurs even before the development of the clinical disease. This simple test which can be readily carried out in routine clinical examinations is capable of revealing tissue damage long before the development of symptoms. This test would be a valuable one in epidemiological studies.

Fibrin-nitrogen content was estimated in a series of 20 cases of epidemic dropsy. The results suggest that the sedimentation rate, the cell volume and the fibrin content are interrelated. An increase of fibrin leads to an increase in the sedimentation rate provided the cell volume is constant. An increase of cell volume decreases the sedimentation rate provided the fibrin content is constant.

throughout the 24 hours as two shifts of 12 hours each were being worked daily. We cannot find any reference to mosquitoes being found living and thriving at this depth reported previously in the literature.

It was also noticed, however, that certain of the pools contained prawns as well as mosquito larvae and pupae and further that where the prawns were more numerous the mosquito larvae and pupae were fewer, while in other more recent pools the reverse was found to hold good. The prawns were quite small and had apparently got into the mine in the moist sand which was used for stowing.

As this seemed to be a new and important natural means of control it was decided to investigate the problem and specimens of both the prawns and the mosquito larvae were brought down to Calcutta. Research was somewhat delayed for various reasons but in due course the prawns were identified by the Zoological Survey of India as *Palæmon lamarrei* Miln. Edw., which is a hardy fresh-water species found everywhere in the plains of India. The life history of *Palæmon lamarrei* has not yet been worked out, but if, as is usual, the eggs are attached to the mother until they hatch, the prawns themselves may enter the mine in the moist sand. If the eggs are laid free, they may be washed in with the sand in this form. We seem to remember an inquiry in a popular song some time ago as to whether prawns made good mothers and the answer certainly does seem to be in the affirmative, even if zoologists have not yet completed their research on the problem.

It was found that the prawns could, on an average, consume nearly three *Culex fatigans* larvae each per day. This is a very poor rate of consumption compared with a larvivorous fish of the *Gambusia* family, but on the other hand it is unlikely that these fish would flourish in darkness or in such shallow pools. In addition there would be the extra expense of having to introduce the fish into the mine if they were to be tried out as a means of control. It was found however that *Gambusia* fish—at any rate in the aquarium—could eat the prawns, although they were more of a mouthful than the mosquito larvae on which they normally fed.

We both revisited Saltore when the laboratory work was completed and found that the prawns had apparently completely cleared that section of the mine where breeding had originally been noticed. Climatic conditions and the state of the pools had remained much the same and there were still plenty of miners about to provide a good supply of blood. Another section of the mine about two miles away where there had been a mosquito nuisance but where there were no prawns was also visited and a few adult species of *Culex fatigans* were seen. In this area, however, coal 'winning' was over and 'goafing' was in progress. This requires a much smaller labour force in the immediate

vicinity and involves the formation of a tremendous amount of dust when the pillars are removed and the roof actually falls. Thus most of the nearby pools were covered with fine coal dust which is probably effective as a larvicide. Another part of the mine is now being worked where mosquitoes but no prawns are present, and we have suggested introducing a few prawns into the pools in this area to see if it also can be cleared of mosquitoes. We have just had an *ad interim* report from the manager to the effect that neither the prawns nor mosquitoes are doing very well at the moment as the pools are constantly being disturbed by the work of the miners.

Sand stowing is now being enforced in more and more mines in both the upper and lower fields, and thus more evidence of this natural means of mosquito control should be observed in the—probably numerous—mines in which mosquitoes are breeding. We have so far not seen or heard of any *Anopheline* species breeding below ground, but there are plenty on the surface and there is also a considerable amount of human malaria present. We feel therefore that the more research and publicity the prawns get in their struggle for existence the better conditions will be for men working in the mines. The prawns may quite likely prove useful to a limited extent in the surface control of malaria even if infection with this scourge has not yet started to take place below ground. So far they do not appear to have been recognized as a possible means of larval control by malariologists.

At Saltore where mine water is now pumped up, filtered, and then chlorinated before it is used in the *dowrabs*, etc., numerous prawns were caught in the settling tanks and tended to clog the filters. We do not think however this should be counted against them as they are edible and can be served up in many palatable forms to both coolies and managers alike. It will surely be an added joy when eating prawn curry to know that the prawns have got fat in helping to fight our mutual enemy—the mosquito.

Our thanks are due to Messrs. Bird & Co., their Chief Mining Engineer and their manager at Saltore for all the facilities and help they have given us.

A Mirror of Hospital Practice

AN UNUSUAL COMPLICATION AFTER OPERATION FOR REMOVAL OF TONSILS AND ADENOIDS

By P. V. CHERIAN, M.B., B.S., D.I.O., F.R.F.P.S., F.R.C.S.E.
Surgeon in charge, Ear, Nose and Throat Department,
Government General Hospital, Madras

Case 1.—Female, aged 12 years, Anglo-Indian, was admitted into hospital in July 1930 for removal of tonsils and adenoids. The operation was done on the day of admission but the post-operative progress was

not satisfactory. The girl was running a slight temperature and there were white sloughs in both tonsillar fossae. An intramuscular injection of colloidal silver (2 c.cm.) was given on the third day without any beneficial effect. The throat now appeared very septic with marked sloughing. A smear was taken and the bacteriologist gave a positive result for diphtheria from smear and culture. The patient died the next day in spite of usual treatment for diphtheria. On enquiry from the parents it was found that a younger brother of the patient was suffering from diphtheria.

Case 2.—A male, Indian, aged 7 years, was operated upon for enlarged tonsils and adenoids on 10th January, 1939, and was discharged the same evening. Three days later the child was brought back with two white patches on both lips. These looked like diphtheritic membranes. Bacteriological examination confirmed the diagnosis. The child made an uneventful recovery under serum treatment. There was no history of any exposure to infection in this case.

Diphtheria used to be a rare disease in India especially among the Indians. Most of the cases were among European and Anglo-Indian children. But towards the latter half of 1936 there was almost an epidemic in Madras affecting both the European and Indian population. Since then we regularly see a number of cases among Indians, mostly among school-going children.

The two cases reported above are the only instances of this complication during the last 12 years in nearly twenty-thousand operations for removal of tonsils and adenoids. If the presence of a case of diphtheria at home in the first case had been brought to my notice no operation would have been done at that time. But the second case is entirely different.

I have not read about this complication in any textbook or journals and so I am reporting these cases as of interest.

A CASE OF DACRYOPS

By RAM PRASAD TREHAN, L.S.M.F., P.S.M.S. (U. P.)

*Medical Officer In-Charge, Atarra Dispensary,
Banda District, U. P.*

A GIRL, aged 3 years, was brought to this dispensary on 18th February, 1940, by her relatives for the treatment of:—

(i) Epiphora from the right eye for last 6 months. (ii) A swelling in the upper part of the right eye which was increasing in size gradually for the last 6 months.

The left eye on examination was found to be perfectly normal.

On examination of the right eye I found that (i) Interpalpebral aperture was narrowed. The upper lid of the right eye was on a lower level than that of the left eye. (ii) Marked epiphora from the eye was present. (iii) Lachrymal passages were quite normal. (iv) Bulbar conjunctiva was quite normal. (v) In the upper fornix a whitish swelling of the size of three-quarter of an inch by half an inch was seen. This swelling became much more marked on evertting the upper lid when it was seen extending on the inner aspect of the upper lid to about one-quarter of an inch above the lid margin and above the limbus. This swelling was cystic in feeling. (vi) Rest of the eye was quite normal.

The only such swellings in the eye in the upper fornix could either be dacryops, which is the name given to the cystic swelling in the upper fornix due to retention of secretion owing to blockage of one of the lachrymal ducts or a retention cyst of the Krause's gland.

The position of swelling is only the differentiating point between the two.

The case having been diagnosed as a dacryops, the patient was operated upon on 18th February.

After thoroughly cocainizing the eye and irrigating it with boric lotion, the cyst was incised by a cataract knife, when about 1 c.cm. of crystal-colour fluid, just like tears, came out and with the escape of this fluid the swelling completely disappeared.

The patient was kept under observation for one day more. The patient had no more epiphora and was discharged next day with instructions to come back if the swelling reappears. The patient has not come back so far.

The point of interest in this case lies in the rarity of this condition.

I am much indebted to Dr. K. S. Dikshit, P.M.S., Civil Surgeon, Banda, for allowing me to publish this case.

RECOVERY OF SPIRILLUM MINUS FROM THE PERIPHERAL BLOOD OF A RAT-BITE FEVER CASE BY EXPERIMENTAL INOCULATION INTO A CLEAN MOUSE

By R. ROW, M.D. (Lond.), D.Sc. (Lond.)

S. D. AMBEGAONKER, M.B., B.S., M.R.C.P. (Lond.)
and

Y. M. BHENDE, M.B., B.S.

(From the Pathology Department, P. G. Singhanee Hospital, Bombay)

L. G., aged 10 years, was admitted into the P. G. Singhanee Hospital for fever with occasional exacerbations (duration 20 days), on 14th August, 1940. He gave a history of a rat bite on the left great toe about five weeks before admission. The wound caused by the rat bite soon healed with some household remedies, leaving a scar. He started getting fever after being well for about 17 days. He was free from any skin lesions for which a close watch had been kept, nor were any joint pains complained of. The following temperature record shows the nature of the fever after his admission into the hospital:—

Date	6 a.m.	10 a.m.	6 p.m.	10 p.m.
14-10-40	—	—	102.5	101.5
15-10-40	97	98	98.0	101.0
16-10-40	97	97	98.0	101.5
17-10-40	97	97	97.0	97.0
18-10-40	97	97	98.0	100.5
19-10-40	97	97	99.5	101.0
20-10-40	100	98	99.0	99.0
21-10-40	99	99	100.0	101.0
22-10-40	98	98	99.5	100.0
23-10-40	99	98	98.0	100.0
24-10-40	99	99	99.0	101.0
25-10-40	97	98	98.0	98.0

The blood showed no malarial parasites nor any spirilla and the blood picture was as follows:—

Red corpuscles	..	3,420,000 per c.mm.
Leucocytes	..	10,500 "
Hæmoglobin	..	55 per cent.
Polymorphonuclears	..	70 "
Lymphocytes	..	27 "
Monocytes
Eosinophils	..	3 per cent.

Widal test was negative for *Bacillus typhosus*, *paratyphosus A* and *B*.

Urine showed a large amount of albumin, red corpuscles, pus cells and granular casts. No acid-fast organisms were found.

Sputum showed no acid-fast organisms.

X-ray report was 'no infiltration'.

It was felt desirable to examine his blood during the height of his fever, so as to ascertain if one could isolate

any spirilla by infecting a clean mouse. The patient's peripheral blood was examined under dark-ground illumination on 14th August, 1940, with negative results. A part of the centrifuged deposit of one c.c.m. of this blood in citrated saline was injected intraperitoneally into a clean mouse. This animal showed heavy infection of *Spirillum minus* in its peripheral blood on 26th August (12 days after inoculation), although when examined on the 8th day none were found.

One cannot say if the kidney lesion of this patient was caused by the spirochaetal infection.

The recovery of *Spirillum minus* in this case is of interest in that with an experimental inoculation into a clean white mouse it is possible to demonstrate the presence of *Spirillum minus* in the peripheral blood of a patient with a clear history of rat bite, even in the absence of skin lesions and with no other manifestations than an irregular obscure fever with occasional exacerbation and therefore one may feel justified in recording this fact.

[Note.—Cases of this nature though uncommon are not unknown, and recovery of *S. minus* by inoculation of peripheral blood into mice is by no means an uncommon procedure. Also kidney irritation as a result of this infection is recognized to occur occasionally, especially in children.—Editor, I.M.G.]

THROMBOPHLEBITIS OF THE CAVERNOUS SINUS

By RAI BHADUR B. B. HAJRA, M.B.

Civil Surgeon, Bakarganj

and

N. DAS, M.B.

Assistant Surgeon, District Hospital, Barisal

THROMBOPHLEBITIS of the cavernous sinus is a condition where, with expectant treatment, practically all cases die from septicaemia, meningitis, etc. The numerous tributaries and effluents of this sinus render it a very common site of infection. Boils and infections of the 'dangerous area of the face', that is, the upper lip, septum of the nose, and the adjacent area, are by far the commonest cause of this dreaded lesion. The anterior facial vein which drains the dangerous area has no valves and any clots therein may easily be detached and transferred to the cavernous sinus as the result of the massage to which it is subjected by the movements of the facial muscles. Thrombosis of the sinus may however also occur by extension of inflammation through its wall. It is now becoming increasingly recognized that timely and judicious surgical intervention and heroic doses of sulphonamide can save many an otherwise hopeless case. Notes of a few illustrative cases are given below:—

Case 1.—A Mohammedan boy, aged 10, had a boil on the tip of his nose which he scratched eight days previously. Spreading swelling of the face, suffusion of the eyelids and proptosis of the left eye followed. On the eighth day he was seen to have swelling of the entire face, chemosis and oedema of the left upper lid and root of nose; proptosis of the left eye, complete ophthalmoplegia with high fever and toxæmia.

The following treatment was instituted:—

(1) Antistreptococcal serum 10 c.c.m. daily—two such.

- (2) Sulphanilamide tablets (Albert David, Ltd.)—two tablets four hourly—two such, one tablet six hourly—four such, one tablet eight hourly—three such, half tablet eight hourly—six such.
- (3) Locally compress with lotio hydrarg. perchlor. 1 in 4,000. Lotio protargol 5 per cent dropped into left eye.

The patient responded marvellously and in 48 hours he was afebrile. On the sixth day of the commencement of this treatment he was given normal diet. Unfortunately the father of the child persistently refused to have the eye out which was sloughy and proptosed and took away the patient against medical advice.

Case 2.—A well-developed Hindu youth, aged 32, had a razor cut five days previously on the right cheek. This developed into an infected wound associated with high temperature and low delirium. The right half of the face became swollen with suffusion of the right eyelids. On the seventh day his temperature rose up to 104°F. The next day the right eye was proptosed and he was having swinging temperature with rigor. Unfortunately sulphanilamide was not given except at this stage. It was diagnosed as cavernous sinus thrombosis and the eyeball was enucleated in spite of its not being blind. The ophthalmic vein was found to contain purulent clots and the superior orbital fissure was enlarged and a drain was put in the cavernous sinus. The first part of Eagleton's operation in such cases, viz., ligature of the common carotid artery did not appear to be very sound being rather too severe for so ill a patient. After a prolonged convalescence the patient recovered.

Case 3.—A Mohammedan woman, aged 20, had a boil on the cheek below the right ear with oedema around. At first she was not very toxic. On the sixth day her condition became worse, temperature rose up to 103°F. with oedema spreading towards the inner canthus of the right eye and the eyelids were suffused. The cavernous sinus being in immediate danger the right angular vein was ligatured under local anaesthesia by novocain 1 per cent and sulphanilamide administered in heroic doses. Lotio hydrarg. percilor. compress was given locally. Rapid improvement followed and the patient was discharged a fortnight later.

Case 4.—A man, aged 35, was admitted with swelling and oedema of the entire face and scalp, proptosis of the right eyeball, suffusion of left eyelids, temperature ranging between 100 and 104°F., and mild delirium. The left angular vein was tied and antistreptococcal serum was administered in heavy doses. Besides local treatment, stimulants and glucose were given as usual. Sulphanilamide was not given in this case. The patient expired on the eleventh day of disease. Operative interference could not be done on account of the party refusing it and sulphanilamide was not administered because it was not then available in an injectable form.

Infection of the face has a sinister reputation and the complication which heralds the fatal issue is thrombosis of the cavernous sinus; sulphanilamide therapy, as in many other dreadful diseases, has a notable place in the treatment of thrombophlebitis of the cavernous sinus. It has been seen that the combination of serum and sulphanilamide is certainly better than serum alone and probably also better than sulphanilamide given alone. A simple and small operation like ligature of the angular vein, if performed in time, may save a life. Eagleton's combined operation of ligature of the common carotid and enucleation of the eyeball is not, in our opinion, very sound and is apparently too severe for so ill a patient. Combined with sulphanilamide enucleation with draining of the cavernous sinus, if necessary, is certainly less drastic and more efficacious.

Indian Medical Gazette

JANUARY

THE FUTURE OF MEDICAL ORGANIZATION IN INDIA

EARLY last year we emphasized the need for better co-operation amongst the medical services in India; the occasion was an address by Lieut-General G. G. Jolly, the director-general of the Indian Medical Service, to the Delhi Maternal Services Co-ordination Committee, in which he pointed out that maternity and child welfare constituted one of the fields in which the preventive and the relief medical services might clash and their work overlap, or in which they might make contact later leading to a fusion that would spread to other medical fields, until all their activities were as completely co-ordinated as their aim, the alleviation of human suffering by the banishment of disease, was unified. We attempted to trace how the rational, though slow, steps in the medical organization in this country, through their failure to keep up with a changing environment, had led to an irrational state of affairs, and we concluded with these words:— We believe that the time has passed when this artificial division [i.e., of the preventive and relief medical services] can serve any useful purpose, and that the next move must be the unification of the direction of the civil medical services. We do not suggest that the reform is an urgent one; on the contrary, we do not believe that there are yet available sufficient men with the necessary wide experience from whom the directors of medical services in the provinces must be selected, for the sanitary outlook and sanitary experience will be essential qualifications. The present system has worked well for many years and with a spirit of willing co-operation between the heads of the respective departments in the different provinces, it will probably continue to do so, but eventually, as medical science has but one aim, unification of direction is inevitable.

In the present number we have given an extract from Sir Ram Nath Chopra's presidential address to the National Institute of Sciences of India; in this address he has suggested the establishment of a Federal Ministry of Health for India. This seems to us not only to be in tune with other changes that are taking place in the government of this country but to be logically the next step in the evolution of the medical organization in India; such a ministry would have executive authority only with reference to health subjects reserved for the central government by the Government of India Act of 1935, or by any future Act, and would be mainly an agency for co-ordinating and advising similar health

organizations in the various provinces. By this means, all medical and closely allied subjects, whether they were associated with prevention or relief, would come under one government department with a minister and a single executive head, who might well be called the *director-general of Indian medical services*.

In this Federal Ministry of Health there would of course have to be numerous sections, each with an expert adviser. The division of the work of the ministry that we visualize would be on the following lines:—

Port Sanitation, Quarantine Service, and International Health, including liaison with foreign and international health organizations.

Public Health, Environmental, including

Sanitary Engineering: water supplies, drainage, and refuse disposal, housing and town planning, and health aspects (anti-malarial) of rivers, irrigation, railway, road and other engineering.

Nutrition: food and drug administration, and drug addiction.

Industrial Hygiene.

Pilgrims.

Public Health, Special, including

Epidemic and Infectious Diseases.

Malaria, Tuberculosis, Leprosy, and Venereal Diseases.

Maternity and Child Welfare.

School Medical Service.

Public Health, Information and Propaganda.

Medical Education—in close co-operation with the Indian Medical Council and the universities.

Medical Relief, including

Rural Medical Relief.

Hospitals.

Health Insurance.

Medical Supplies, including cinchona and other indigenous supplies and manufacture.

Prisons.

Lunacy.

Scientific Research.

In Great Britain the Ministry of Health covers much the same field, but the emphases in the two countries naturally differ; for example, in England, industrial hygiene is far more developed and is provided with a separate department, and rural medical relief is correspondingly a less difficult problem. Similarly, pilgrimages, the major epidemic diseases, and malaria are particularly Indian problems; nor does the British Ministry of Health have to concern itself with medical education to such an extent as would an Indian one.

As well as the Federal Ministry of Health at the centre, each province would have its own ministry of health with its own minister and chief medical officer—what he is to be called is a secondary, though not entirely unimportant, matter; the term 'surgeon-general' has the sanction of tradition but is misleading in both its components, for not necessarily, in fact quite improbably, will he be a surgeon, nor, as far as the future is concerned, will he always hold military rank. The provincial ministries will have their various sections corresponding more or less to those of the central organization. The senior medical officers, whatever they are called, must be men of wide experience in both preventive and curative medicine, as also should the heads of the various sections; the intermediate

members of the medical organization may have to be specialists—surgeons, physicians, gynaecologists and pediatricians, tuberculosis, leprosy and venereal disease experts, sanitary engineers, chemists and analysts, professors and teachers, alienists, and research workers, but the ultimate medical unit, the rural dispensary medical officer, may have to widen his scope and be responsible for both medical relief and environmental hygiene, the latter possibly with the help of a sanitary inspector, and he will also have to be the inspirer of welfare work amongst the lay community.

Sir Ram Nath, in his address referred to above, has suggested Federal and provincial organizations on very much the same lines as these; he has also emphasized the fact that the chief medical officers and the sectional heads will have to be men of wide experience, and he has suggested that during their probationerships, in order to widen their outlook, they should be given the opportunity to act as deputies in a number of different sections in the department—a small detail of administration but one that is of the utmost importance, for the success of the scheme will depend on a proper understanding between different sections of the department, as well as on the official liaison that will be effected through the common head of the department.

We are not suggesting that there should be any sudden and revolutionary change in the medical administration at the centre or in the provinces, for though, as Sir Ram Nath has pointed out, there is already in existence much material which could be adapted to the new

organization in the course of a few years, yet to provide the full complement of suitably trained men for the scheme, a considerable change in the outlook of those responsible for medical education will have to be effected.

The position with regard to public health training a few years ago was that the men who had taken their diplomas often found difficulty in obtaining suitable employment; this is to some extent being remedied and the importance of this training is being appreciated by local bodies responsible for appointments; but not yet to the extent that it should be. The medical organization that we have visualized would absorb a very much larger number of men than is at present available or would be likely to be turned out by our present public-health-teaching organization, so that this will have to be extended considerably. Beyond this there will have to be an extensive change in the medical students' curriculum and they must be imbued with the preventive outlook to a far greater extent than they are at present.

All these changes will have to precede the full establishment of the 'new order' in the medical organization of this country that we have outlined, so that this matter should be considered as very urgent. On the other hand, it is useless to turn out a large number of public-health-diploma holders if they are not going to find suitable work, and therefore the sooner the projected organization is clearly laid down and the Federal and provincial ministries of health are formed, even if at first on a skeleton basis, the sooner will the full scheme come to fruition.

HÄMATOLOGICAL TECHNIQUE

PART VII

By L. EVERARD NAPIER, F.R.C.P. (Lond.)

and

C. R. DAS GUPTA, M.B. (Cal.), D.T.M.

(From the School of Tropical Medicine, Calcutta)

(10) White cell differential count

WHEN making a white cell differential count, an attempt should be made to fulfil the following requirements:

(i) The film should be uniformly spread and should be neither too thin nor too thick—the ideal film is one where the margins of the red cells when seen under the microscope just touch one another without over-lapping (*vide*, Part VI).

(ii) The film should occupy the middle two-thirds of the slide.

(iii) There should be no 'tails' at the end of the film.

(iv) The drop should be a small one so that the whole may be utilized in making the smear;

as, if only a portion of a large drop is used, this portion may not contain a fair sample of the cells (e.g., the large cells tend to sink to the bottom of the drop).

(v) The cells should be stained well and there should be no debris in between or on the cells.

A well-stained film shows—

red cells—an orange-buff colour,

lymphocytes—with pale blue cytoplasm, and neutrophil granules—a dull lilac.

Number of cells to be counted

This will vary directly with the total white cell count, the higher the total count the larger is the number of the cells that should be counted to get a correct proportion of the different cells. The following rule may be taken as a guide, but need not be followed rigidly:—

Count 100 cells when the total white count is below 5,000 per c.mm.

Count 200 cells when the total white count is above 5,000 per c.mm. but below 10,000.

Count 300 cells when the total white count is above 10,000 per c.mm. but below 20,000.
Count 400 cells when the total white count is above 20,000 per c.mm.

The differential count should be done with an oil-immersion lens (1/12) and an $\times 5$ eyepiece with a $\times 10$ eyepiece at hand. This magnification will enable one to see the details of the cells distinctly, but a higher magnification, given by the $\times 10$ eyepiece, may sometimes seem desirable, e.g., in case of doubt arising as to the true identity of a cell. In actual practice it will be found that one seldom changes the eyepiece.

The microscope must be fitted with a mechanical stage that allows easy movement in either the horizontal or the vertical plane. Northern daylight is preferable to artificial light, as it shows the true colour of the different cells. If artificial light has to be used a blue filter should be placed in front of the light itself or under the condenser of the microscope.

Procedure.—Place the stained blood film on the mechanical stage of the microscope and fix it securely; with the low power (2/3 objective) make a rapid survey of the different parts of the film, to find out if the requirements mentioned above are fulfilled. If not, it is recommended that another, properly made, film should be stained, for to attempt to make a differential count on an unsatisfactory blood film is laborious and irritating, and the result obtained is never accurate.

If the blood film is satisfactory, put a drop of cedar-wood oil on the smear, rotate the oil-immersion lens into position, open the diaphragm fully and raise the condenser to get the maximum amount of light. With the coarse adjustment, lower the oil-immersion lens just to touch the stained film through the cedar-wood oil; then, looking into the microscope, gently raise the lens until the cells are seen, and finally manipulate the fine adjustment until the focus is accurate.

The distribution of the white cells in the different portions of the blood films depends on their size; the larger and heavier cells, e.g., neutrophils, eosinophils, and large mononuclears, are mostly found along the edges and at the tail end of a smear, while the smaller and the lighter cells, e.g., the lymphocytes, tend to occupy the middle of the film.

Therefore, in order to get an absolutely correct differential count every cell in the blood smear on the slide, or on both the coverslips used in making the smear if the coverslip method is used, must be counted and classified, and the percentage calculated. This takes a long time, particularly if the smear is a large one; it is therefore advisable to make as small a smear as possible.

A very small smear can be made by taking a large drop, with the corner of a slide touching this drop, transferring a portion of it to another slide, and making a smear, but this must be

done quickly before the cells settle (*v.s.*). If the cells counted on a *whole* small smear are over a hundred, it is better to accept this than to supplement it by a counting part of another film.

Otherwise, a smear is made from a small (initial) drop and one of the methods suggested below is adopted. From neither of these methods will the error be very great.

(i) Start counting at a point A, near the proximal end of the smear and along one edge, moving the slide longitudinally, counting and classifying the cells all the time, up to B which is beyond the end of the film; move the slide the breadth of one or two fields to B' and again move back along the whole length of the film to C, which is beyond the proximal end of the film; move across to C' and then back again up and down the film. Continue to do this until about the middle of the film is reached, or until a sufficient number of cells has been counted, but always end the counting at the end of the film (*vide figure 1*).

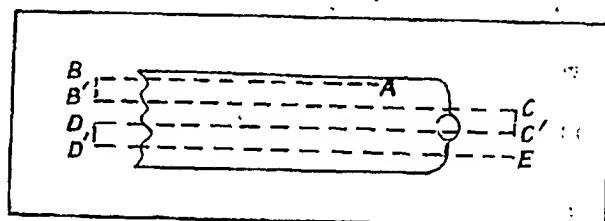

Fig. 1.

By this procedure you will have included one edge, and one or two fields from the rest of the film. The majority of the heavy cells are drawn to the distal end and only a few to the sides, so that the discrepancy will not be great if, after counting one edge, you count a little more or a little less of the rest of the film. On the other hand, it is important to finish at the end, so that you will have covered an even proportion of body and tail of the film. For this reason an exact figure should not be aimed at, but the point of stopping, like the point of starting, should be at the proximal end. The percentages of the different cells are then calculated.

Example.—Suppose that in making a differential white-cell count of a blood film there are 141 neutrophils, 63 lymphocytes, 12 monocytes, and 9 eosinophils, i.e., 225 cells altogether, the percentage of the different cells are calculated, and are:—

$$\text{Neutrophils} = \frac{141 \times 100}{225} = 62.6 \text{ or } 62.7 \text{ per cent.}$$

$$\text{Lymphocytes} = \frac{63 \times 100}{225} = 28.0$$

$$\text{Monocytes} = \frac{12 \times 100}{225} = 5.3 \text{ or } 5.3$$

$$\text{Eosinophils} = \frac{9 \times 100}{225} = 4.0$$

(ii). *Fourfold meander technique.*—Though this method is recommended in most textbooks

we consider that it allows greater scope for individual variation in procedure, and we prefer the previous method; the method is as follows :—

From a point at the edge of the film move towards the centre of the film for about 4 'fields' then, using the other mechanical-stage adjustment, move about 4 fields towards the proximal end of the film, then back towards and beyond the edge, move a few fields towards the proximal end, and repeat the process until 50 cells have been counted and classified. This process should be repeated in four different places at the edge of the film, on either side and near each end of the film (*vide* figure 2).

Example 1.—

														Total	Per cent
N —	/	/	/	/	/	/	/	/	/	/	/	/	132	= 68.0	
L —	/	/	/	/	/	/	/	/	/	/	/	/	51	= 26.3	
M —	/												7	= 3.6	
E —	/	/											3	= 1.5	
B —	/												1	= 0.5	
													194		

II. Another method is to memorize the numbers of the two main cell types until one of the other types is encountered, then to enter the count on your prepared list, and begin again. Thus :—

Example 2.—

	..	10	12	14	17	20	4	10	14	1	20	10		Total	Per cent
Neutrophils	..	10	12	14	17	20	4	10	14	1	20	10		132	= 68.0
Lymphocytes	..	4	3	5	8	5	1	8	4	1	10	2		51	= 26.3
Monocytes	1	1	1	1	..	1	1	..	1	..		7	= 3.6
Eosinophils	..	1	1	1		3	= 1.5
Basophils	1		1	= 0.5

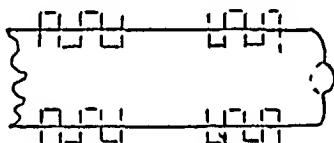

Fig. 2.

Recording the results

Except in cases of leukaemia and some rare pathological conditions, the types of white

Example 3.—

	..	18	17	10	14	16	14	20	11	120	Total	Per cent
Neutrophils	..	18	17	10	14	16	14	20	11	120		= 60.0
Lymphocytes	..	6	5	12	8	7	9	4	9	60		= 30.0
Monocytes	..	0	3	2	1	2	1	1	3	13		= 6.5
Eosinophils	..	1	0	1	1	0	1	0	2	6		= 3.0
Basophils	..	0	0	0	1	0	0	0	0	1		= 0.5

cells which are usually seen in the differential count of a peripheral blood film are neutrophils, lymphocytes, monocytes, eosinophils, and basophils, in the order of frequency in which they are encountered. As the slide is moved from one field of vision to another, the examiner must record both the total number and also the types of cells encountered.

This may be done in different ways :—

I. The usual method is to write down on a piece of paper the names of the cells in the order of frequency in which they usually occur in the peripheral blood and to put a vertical stroke against each cell which is seen in the field of vision, making the fifth stroke cross the other four, so that the strokes in groups of five are easily counted (*vide* example 1). When all the cells in the film, or in the case of a large film, in the area decided upon, have been counted, they are totalled, and the percentage calculated.

Example 1.—

N —	/	/	/	/	/	/	/	/	/	/	/	/	= 68
L —	/	/	/	/	/	/	/	/	/	/	/	/	= 32
M —	/												= 5
E —	/	/											= 6
B —	/												= 1

The numbers against each type are added and the percentages calculated.

III. A quicker method, which can be learnt with a little practice, is to remember the numbers of the different types of cells in the traditional sequence neutrophil, lymphocyte, monocyte, eosinophil and basophil until 25 cells have been counted; the number of each type counted is entered against the respective name on a piece of paper and when the required number of cells have been counted, they are totalled and the percentages calculated.

	..	18	17	10	14	16	14	20	11	120	Total	Per cent
Neutrophils	..	18	17	10	14	16	14	20	11	120		= 60.0
Lymphocytes	..	6	5	12	8	7	9	4	9	60		= 30.0
Monocytes	..	0	3	2	1	2	1	1	3	13		= 6.5
Eosinophils	..	1	0	1	1	0	1	0	2	6		= 3.0
Basophils	..	0	0	0	1	0	0	0	0	1		= 0.5

Method I is simple and fool-proof, but slow; method II is also simple and saves the repeated interruptions of method I; method III is very popular, but tends to make one stop at a round number and thereby simplify the calculation, which is a procedure not in the best interests of accurate countings.

In methods I and II, theoretically one has to stop periodically and add up all the figures to see if sufficient cells have been counted, but this can be obviated by the use of a mechanical counter, e.g., the Veeder-Root hand tally. The 'counter' fits nicely into the hollow of the palm and is conveniently kept in the left hand. The knob is pressed with the thumb each time that a cell is seen and the numbers are at once recorded on the dial. The total number of cells counted at any time during the process of the differential count can be seen by simply looking at the dial of the counter.

Expressing the results

It is customary to express the result in the white-cell differential count as a percentage of the various cells encountered, without any reference to the total white cell count. This does not always convey the full significance of the observation, and both percentage and absolute figures should be given.

The absolute figures are readily obtained by striking out the last two zeros of the total leucocyte count, or moving the decimal point back two spaces, and multiplying each percentage by this figure, as in the example given below :—

Example.—(A fairly normal count).

Total white-cell count—7,500 per c.mm.

Differential white-cell count—

	Per cent	Total per c.mm.
Neutrophils	.. 68.0	5,100
Lymphocytes	.. 24.0	1,800
Monocytes	.. 5.0	375
Eosinophils	.. 2.5	187
Basophils	.. 0.5	37

Now, if the patient were to take some toxic drug which reduced the neutrophils to a low figure, say to 500 per c.mm., but did not affect the other leucocytes, the total count would now be 2,900 per c.mm. and the percentages—

	Per cent	Total per c.mm.
Neutrophils	.. 17.2	500
Lymphocytes	.. 62.1	1,800
Monocytes	.. 12.9	375
Eosinophils	.. 6.4	187
Basophils	.. 1.3	37

In this count the attention is attracted by the high lymphocyte and monocyte percentages, whereas actually these cell elements are normal and all that has happened is a decrease in neutrophils.

Again, in asthma there may be a sudden high rise in eosinophils which reduces considerably the percentage of neutrophils, even in cases where there has been an actual increase in this element, so that again a wrong impression is made.

Therefore, a differential count should always be given in absolute figures as well as in percentages.

Normal white-cell counts.—The normal leucocyte count in an adult is usually given as 7,000 to 9,000 per c.mm. Some of our findings in Indian populations are given below :—

From records of 114 normal females in which the full differential counts are available, we have calculated the following means :—

	Percentage Per c.mm.	
Neutrophils	..	62.6 4,507
Lymphocytes	..	26.9 1,937
Monocytes	..	5.5 396
Eosinophils	..	4.8 346
Basophils	..	0.2 14

It will be noted that the monocyte counts are all above the usual normal figure, but especially those in Assam, where malaria is very prevalent. The eosinophil figures are also high compared with European and American standards and they are exceptionally high in the Assam population, where the hookworm-infection rate is nearly 100 per cent.

(11) Cell identification

The first essential for accurate identification of the cells of the blood or marrow is a satisfactory and properly-stained blood film. A well-stained film should show no precipitate on or between the cells, the red cells should stain an orange buff, the neutrophil granules a dull shade of lilac, and in the monocyte the so-called 'azurophil granules' should just be visible—with any of the Romanowsky stains.

The following system is recommended for the identification of different cells.

Granules.—First, ascertain whether the cytoplasm of the cells contains any granules, or not. If there are granules, decide whether the granules are neutrophilic, eosinophilic, or basophilic.

Neutrophil granules are small, uniform in size, uncountably numerous, and stain a dull shade of lilac.

Eosinophil granules are large, round, uniform in size, and stain orange-red with pale centres. They are not so numerous as neutrophil granules—occasionally eosinophil granules take on a bluish stain, even in a well-stained specimen, while in a badly stained one all may be bluish.

Basophil granules vary considerably in size in the same cell, they stain a dark blue-violet colour, which is entirely different from the colour of the nucleus; they are always coarser and fewer in number than the neutrophil or eosinophil granules. The granules are found not only in the cytoplasm, but also they are always found superimposed on the nucleus.

SUBJECTS		Residence	TOTAL LEUCOCYTE COUNT		MONOCYTES		EOSINOPHILS	
Number	Sex		Mean	S.D.	Mean	S.D.	Mean	S.D.
50	Males	Calcutta	6,542	± 1,214	7.00	± 3.91	6.90	± 5.19
128	Females	"	7,162	± 1,765			5.16	± 4.21
24	Males	Assam	8,166	± 2,650	9.44	..	13.76	± 8.8
17	Females	"	8,768	± 2,650	8.35	± 4.32	13.74	± 8.8
25	Males	Cachar	7,111	± 1,759				
25	Females	"	6,456	± 1,755	

TABLE I
Identification of cells without specific granules

Nucleoli	Shape of nucleus	Chromatin structure	Size of nucleus in relation to cell	Cytoplasm	Azurophil particles	Name of cell	Identification mark
Present	Round, oval, or irregular.	Fine Finer than I Relatively coarse	More than three-quarters " " " " two-thirds	Clear light blue Clear deeper blue than I Light blue, opaque	None	Myeloblast Lymphoblast Monoblast	I II III
	Ditto with irregular outline.	Fine, stippled	" " "	Dark grey-blue, ground glass with clear halo around the nucleus.		Megaloblast	IV
Present or absent	Round, oval, or irregular. Kidney or irregular	Coarse Coarser than III	More than half " " "	Clear light blue Light blue—opaque.	May be present	Large lymphocyte Pre-monocyte	IIa IIIa
	Generally round or oval; may be clover leaf.	Coarse; in clumps	More than half in larger cells but almost fills the cell in the smaller ones.	Clear transparent blue May appear only as a thin rim in the smaller cells.	May be present; few; unevenly distributed.	Lymphocyte	IIb
Absent	Horse-shoe or irregular	Coarse clumps or strands.	Half or more	Light, faded blue, opaque	Usually present, very fine, numerous, scattered.	Monocytes	IIIb
	Round or oval	Coarse	More than two-thirds	Ground-glass greyish blue, with a little haemoglobin in some cases.		Erythroblast	IVa
Round	Very coarse	Variable, usually less than two-thirds.	less	Ditto with more haemoglobin.	None	Macroblast	IVb
	Pycnotic (nucleus almost black).	Variable, often less than half.		Grey, reddish-grey, or pink as in the red cells.		Normoblast	IVc
Round or oval	Very coarse, cartwheel appearance; eccentric.	Less than half		Deep greyish-blue ground-glass.	None	Plasma cell	V
	Irregular 'multi-lobed'	Coarse	Variable	Light blue obscured by azure particles.	Present, fine numerous.	Megakaryocyte *	VI

* Mature platelets (VIa) which develop from the megakaryocyte are small (2 to 3 μ) ill-defined structures, not clearly differentiated into nucleus and cytoplasm.

TABLE II
Identification of cells containing granules

Nucleoli	Nucleus	Granules	Cytoplasm	Cell	Mark	REMARKS.
Present ..	Round or oval; relatively fine chromatin structure.	Very few; fine, scattered.	Pale blue. Relatively small amount.	Pre-myelocyte	Ia	This, as well as the other granular cells may be neutrophil, eosinophil or basophil. Basophil pre-myelocytes are rarely identified.
Generally absent.	Round or oval; coarse chromatin structure; may not be very well stained.	Very prominent; coarse.	Very pale blue: variable in amount, but usually more than in Ia; not well seen, as it is covered by granules.	Myelocyte	Ib	In the eosinophil and basophil myelocytes, the cytoplasm is almost entirely covered by granules, and is rarely visible. In the basophil the nucleus also is blurred by granules.
	Bean- or kidney-shaped; coarse chromatin structure.	Granules less prominent than corresponding granules in Ib: numerous.	Large in amount. Very pale blue obscured by granules.	Meta-myelocyte or young forms.	Ic	The basophil meta-myelocyte and staff cells are very difficult to identify.
	Curved rod; coarse chromatin structure.	Finer and more numerous than corresponding granules in Ic.	Large amount. Very pale blue.	Staff (or band)	Id	
Absent	Lobed or segmented, 2 to 5 or more lobes.	Very fine and numerous: light lilac colour.	Large amount. Very light greyish-blue.	Neutrophil polymorpho-nuclear granulocyte.	Ie(i)	
	Usually bilobed; rarely may have more lobes.	Finer than eosinophilic precursor Id(ii), but coarser than Ie(i).	Very pale blue; scarcely seen.	Eosinophil granulocyte.	Ie(ii)	
	Segmentation of the lobes is difficult to make out, but never more than two lobes.	Very coarse; dark violet blue, almost black, often obscuring nucleus.	Very pale blue; scarcely seen.	Basophil granulocyte.	Ie(iii)	

Besides these specific granules, the presence of which characterizes the cells of the granular series, some cells of the non-granular series, e.g., monocytes and lymphocytes, may show some stained particles in the cytoplasm of the cells which have been called 'azurophil granules'. These azurophil particles are of the same colour as the nucleus of the cell in which they occur, but may be paler, brighter, or darker. They vary in size, in depth of staining, and in number. In the lymphocytes the particles are few in number, they are large, coarse, and darkly stained, and occur in small groups in the cytoplasm, while the particles in the monocytes are more numerous, paler and finer, and are more evenly distributed in the cytoplasm.

Having noted whether granules are present or not, and if present the nature of the granules,

employ the following tables for the further identification of the cells:-

Table I gives the cells of the non-granular series, and table II those of the granular series.

The cells of the granular series all originate from the primary differentiated cell of that series, the myeloblast. They are arranged in the table in order of maturation.

The mature neutrophil, eosinophil and basophil have their specific precursors in the earlier cells of the series and these can be distinguished by the size and colour of their granules (*v. s.*); there are, thus, neutrophil, eosinophil and basophil, premyelocytes, myelocytes, metamyelocytes and staff cells.

Table III is a supplementary table to aid in the identification of primary differentiated cells which are already shown in table I.

TABLE III
Identification of the earliest differentiated cells

Name of cell	Nucleoli	Nucleus	Chromatin	Nuclear membrane	Cytoplasm	Auer's bodies
I. Myeloblast	Few, not very distinct.	Round or oval; usually central.	Fine reticulation.	Not distinct and no condensation of chromatin at edges of nucleus.	Clear light transparent blue.	May be seen occasionally.
II. Lymphoblast	Many, very distinct.	Round or oval and central.	Finer reticulation.	Distinct with condensation of chromatin at the edges.	Clear deeper blue.	Not seen.
III. Monoblast	One or two often clean cut.	Round or oval; often folded.	Relatively coarse.	Not distinct and no condensation of chromatin at edges.	Light blue, not so transparent.	Frequently seen.
IV. Megaloblast	Few, appear as irregular gaps.	Round or oval; large.	Fine, stippled.	Not distinct and no condensation of chromatin at edges.	Grey-blue ground-glass, with halo round nucleus.	None.

TABLE IV
Identification of the different nucleated cells of red cell series

Cell	Size	Cell outline	Cytoplasm	Nucleoli	Nucleus	Chromatin
IV. Megaloblast	16-21 μ	Irregular	(i) Dark blue-grey (basophilic). (ii) Polychromatic or eosinophilic (Ehrlich's megaloblast).	Present, few, appear as irregular gaps.	Large; occupies more than two-thirds of the cell; sometimes eccentric.	Fine, stippled, stains lightly.
IVa. Erythroblast	12-18 μ	Regular	Basophilic, polychromatic or eosinophilic.	Absent	Central and smaller than that of (IV); occupies over two-thirds of cell.	Coarse, less reticular, deeply-staining.
IVb. Macroblast	7-14 μ	Regular	Basophilic, polychromatic or eosinophilic.	Absent	Usually central and occupies more than half.	Very coarse, reticular, deeply-staining.
IVc. Normoblast	5-10 μ	Regular	Polychromatic or eosinophilic.	Absent	Sometimes eccentric; may be lobed or clover leaf.	Pycnotic, appears as drop of ink.

The points of difference in the morphology of the different primary cells are very fine and at times it is almost impossible to distinguish one from the other. In cases of leukaemia or anaemia the identification of an individual cell has often to be made, not on the cell alone but on the characteristics displayed by other associated cells; in other words, the cell is judged 'on the company it keeps'.

Table IV is also supplementary. It gives the nucleated cells of the red cell series in order of maturation.

The development of blood cells

We do not propose to discuss the origin of the cells found in the blood stream, for it is a controversial field in which 'unitarians', 'dualists', and 'trialists', of the monophyletic and polyphyletic schools argue with one another to the

confusion of the practical haematologist. We are only concerned with the already differentiated cells, the immediate precursors of the normal and abnormal cells of the peripheral circulation.

It is, however, impossible to avoid controversy altogether, as this is intimately associated with nomenclature which is definitely our domain, for at present much confusion in the literature is due to different writers adopting different names for the same cell, and the same name for different cells.

We have followed the Sabin school in using the word 'megaloblast' for the earliest differentiated precursor of both normal and abnormal red cells, and have used the expression 'Ehrlich's megaloblast' for the haemoglobinized megaloblasts that are encountered in Addison's pernicious anaemia and rarely in other macrocytic anaemias. Some writers refer to 'our' normal

megaloblast as a basophil erythroblast, an early primary erythroblast, a pronormoblast, or even as a haemocytoblast (which name most writers reserve for the common stem cell).

With reference to the other cells, we have taken the view that the granulocytes, lymphocytes, monocytes and platelets have each a separate differentiated precursor cell, and following the usual practice we have called these myeloblast, lymphoblast, normoblast, and megakaryocyte, respectively.

Red cells.—Normally, the red cells originate intravascularly from the endothelial cells of the sinusoidal spaces and capillaries of the bone marrow. The first differentiated cell is the megaloblast. As development proceeds, the megaloblast passes through the stages of erythroblast, macroblast, normoblast and reticulocyte to develop into the mature erythrocyte (*vide schema*). In the process of maturation the nucleus loses its nucleoli very early, so that these are not seen in the erythroblast; the nucleus also loses its reticular structure and becomes gradually coarser and coarser as development proceeds, until in the normoblast it becomes completely pyknotic; after this the nucleus is lost (by fragmentation or extrusion) and the erythrocyte becomes fully mature. The reticulocyte is a stage between the normoblast and the fully-mature red cell, but the reticulations are not seen in a Romanowsky-stained film.

Granulocytes.—The granular cells develop extravascularly from the reticulo-endothelial cells of the bone-marrow. The earliest differentiated cell is the myeloblast.

The first evidence of maturation of the myeloblast is the appearance of granules in the cytoplasm. At first the granules are very fine and few, as in the pre-myelocytes, but gradually they become more numerous and coarser, and are coarsest at the myelocytic stage, after which the granules again become finer and less numerous as development proceeds. In the fully-developed neutrophil polymorphonuclear cells the granules are very fine and numerous. The cells can be differentiated as neutrophil, eosinophil and basophil according to the colour and size of their respective granules, with difficulty at the premeyelocyte stage but quite easily from the myelocyte stage onwards.

In the process of development the nucleus loses its nucleoli; these are ill-defined in the premeyelocyte and are almost always absent from the myelocyte stage onwards. The chromatin structure of the nucleus which is finely reticular in the myeloblast becomes coarser and more condensed as development proceeds, and is very dense at the later stages; this condensation makes the nucleus smaller. The shape of the nucleus too changes from round or oval at the earlier myeloblast, premeyelocyte, and myelocyte stages to kidney or bean shape at the metamyelocyte stage, and then it becomes elongated in the staff, and finally lobulated in the segmented forms.

The cytoplasm which is blue and scanty in the myeloblast loses its colour gradually and becomes more abundant as development proceeds—in the later stages the cytoplasm is hardly visible as it is covered by the granules.

Monocytes.—The monocytes originate from the reticulum all over the body but particularly from that in the spleen. The first differentiated cell is the monoblast; it proceeds through the stage of the premonocyte to the stage of fully-developed monocyte. As development proceeds, the nucleus loses its nucleoli and the fine reticular structure becomes coarser, and very fine and numerous azurophilic particles appear in the cytoplasm of a fully-developed monocyte. The nucleus which is round or oval in the monoblast, becomes slightly indented in the premonocyte, and may take on various shapes in the mature monocytes. (We have made no attempt to differentiate between monocytes and histiocyte; this can only be done by a supra-vital staining process which we are not describing here. Some of the large mononuclear cells in the peripheral blood are undoubtedly histiocytes, whose origin is probably different from that of the monocytes.)

Lymphocytes

The lymphocytes originate mainly from the lymphatic tissue of the lymph glands all over the body and to a small extent from the lymphoid tissue in the marrow. The first differentiated cell is the lymphoblast which proceeds through the stage of large lymphocyte to the fully-developed (small) lymphocyte.

In the process of development the nucleus loses the nucleoli, the fine chromatin structure becomes coarser, and finally pyknotic in the mature cells. The cytoplasm which is definitely blue in the lymphoblast becomes lighter in colour as development proceeds, but is always transparent. In some of the older cells a few coarse irregularly scattered azurophilic particles may be seen.

(12) Technique of sternal puncture

Bone puncture as an aid to accurate diagnosis of blood diseases and to the study of their aetiology has only come into general use during the last few years; the main reason for this was that the methods used for obtaining material from the bones were comparatively difficult, and usually painful, unless an anaesthetic were given, before the Salah sternal-puncture needle was introduced. This handy and inexpensive instrument is now used widely not only in haematological work but in the diagnosis of kala-azar and other protozoal and bacterial diseases. We have used this needle for about four years and have adopted sternal puncture as a routine procedure in all cases of anaemia.

The senior writer described this technique in a paper written in co-operation with Dr. P. C. Sen Gupta,* (Napier and Sen Gupta, 1938);

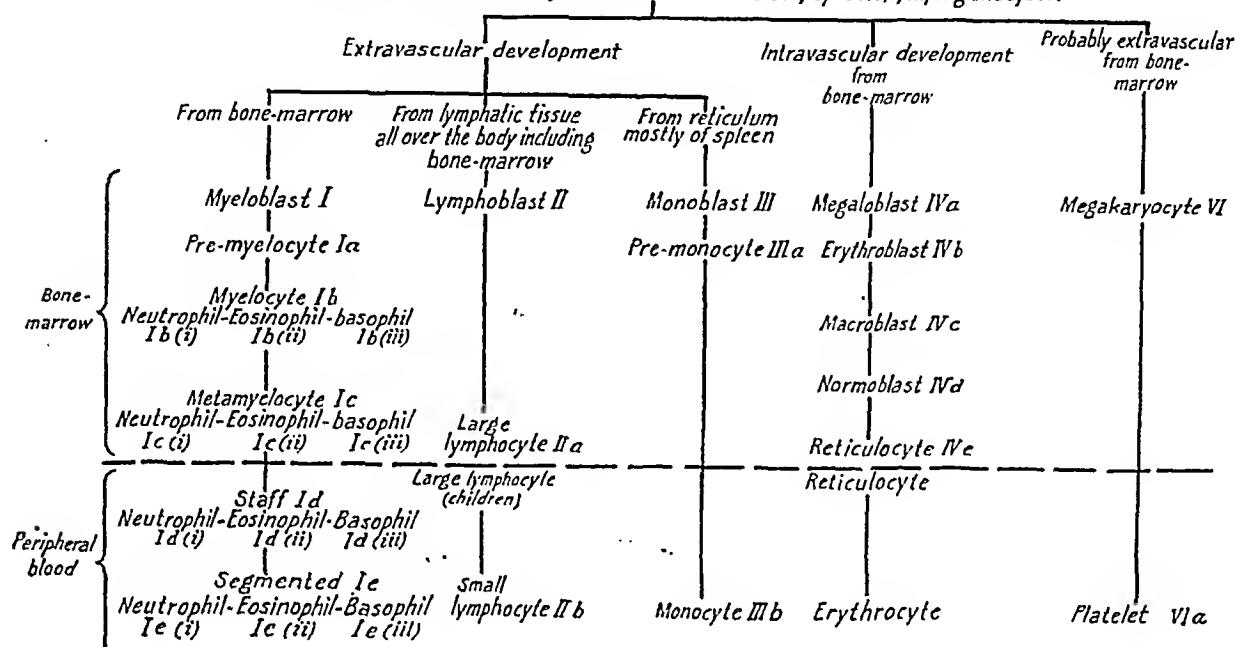

* With whose kind permission the figures from this paper have been reproduced.

since then, as a result of further experience, certain modifications in technique have been introduced and these are incorporated in this description, but the technique described is materially the same as that given in the above-mentioned paper.

steel and the bore is about the same as that of a lumbar puncture needle. The guard C on the needle can be moved so as to adjust the depth of the puncture. Usually the guard has to be fixed at a distance of 1 to 1.5 cm. from the tip, in order that the marrow may be reached. This

Origin of blood cells.

From reticulo-endothelial system in bone-marrow, spleen, lymph glands, etc.

Apparatus required.

1. The sternal-puncture needle.
2. Two Record syringes, 2 c.cm.
3. A pair of scissors and a shaving set.
4. Two per cent solution of novocaine or any of its substitutes. (Pitumeric 4 per cent solution produces good anaesthesia.)
5. Absolute alcohol and ether.
6. Collodion or tincture of benzoin.
7. Cotton-wool, etc.

The needle is dry-sterilized in a hot-air sterilizer in a test-tube. The syringe is sterilized by boiling and then dried thoroughly by first driving out water with alcohol and later alcohol with ether, and finally by drawing in and expelling hot air (through the flame of a gas burner or spirit lamp).

The sternal puncture needle

The Salah needle used for sternal puncture is shown below (figure 3). It is made of rustless

distance will vary with the thickness of the skin and subcutaneous tissue of the thoracic wall; in fat individuals up to 2 cm. may be required and in very emaciated ones less than 1 cm. It may be found advisable to readjust the guard after the needle has reached the periosteum, before it is pushed through the outer plate into the marrow cavity. The stylet A is kept in while the puncture is being made and is withdrawn after the cavity is reached.

Procedure

The hair over the sternum, if there be any, is first clipped with a pair of scissors, shaved with a razor, and the skin finally cleaned thoroughly with alcohol. The best site for the puncture is just to one side of the middle line at the level of the second intercostal space. This area is first anaesthetized by infiltration with a two per cent solution of novocaine, or its substitute.

Some solution is first injected into the skin with a fine needle attached to a 2-c.cm. syringe, then the needle is pushed down to the periosteum and the rest of the solution injected. About one c.cm. is usually sufficient in a thin individual, but more is required where the subcutaneous tissue is deeper. After an interval of five minutes or so, the actual puncture is made.

The apparatus is held with the knob of the stylet in the palm of the hand and the needle itself between the thumb and index finger, the latter on the guard C of the needle. Pressure

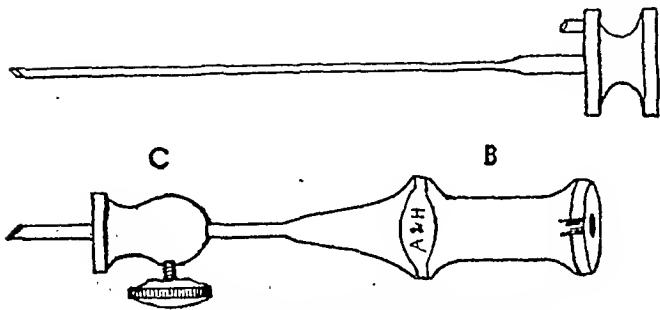

Fig. 3.—Needle B with stylet A removed: movable guard C (actual size).

PLATE I

PLATE I

I. *Myeloblasts.*

- Ia. *Premyelocytes* showing azur particles: the fourth cell, an eosinophil precursor, is slightly more mature than the rest.
- Ib. *Myelocytes*; the cells in the upper are less mature than those in the lower row: the first three in each row are neutrophils and the last two eosinophils.
- Ic. *Meta-myelocytes*; the last two (Icii) are eosinophils (the last cell in the row has not been reproduced well and has lost the red coloration that was apparent in the original drawing).
- Id. *Staff or band forms*, the last two being eosinophils (Idii). (The colour of the last two is too red; the purple colour of the nucleus is sometimes obscured by the eosinophil granules, but not to the extent indicated here.)
- Ie. *Mature granulocytes*, the first three being neutrophils and the last two eosinophils.
- Ib(iii), Ic(iii) and Ie(iii). *Basophils*, myelocyte, meta-myelocyte and mature. The shape of the nucleus is the only feature on which the immature forms are identified. In the original drawing the shapes of the nuclei were just discernible, but in the reproduction they are obscured.

III. *Monoblasts*, the lower two showing Auer's bodies.

IIIa. *Premonocytes.*

- IIIb. *Monocytes*; the second cell in the top row might be classed as a pre-monocyte, but the azur particles are well developed. (There should be more blue colour in the cytoplasm of these cells.)

VI. *Megakaryocyte*; these cells are often proportionately much bigger than the one shown.

VIa. *Platelets.*

Magnification about $\times 1,000$.

Staining—May-Grünwald and Giemsa.

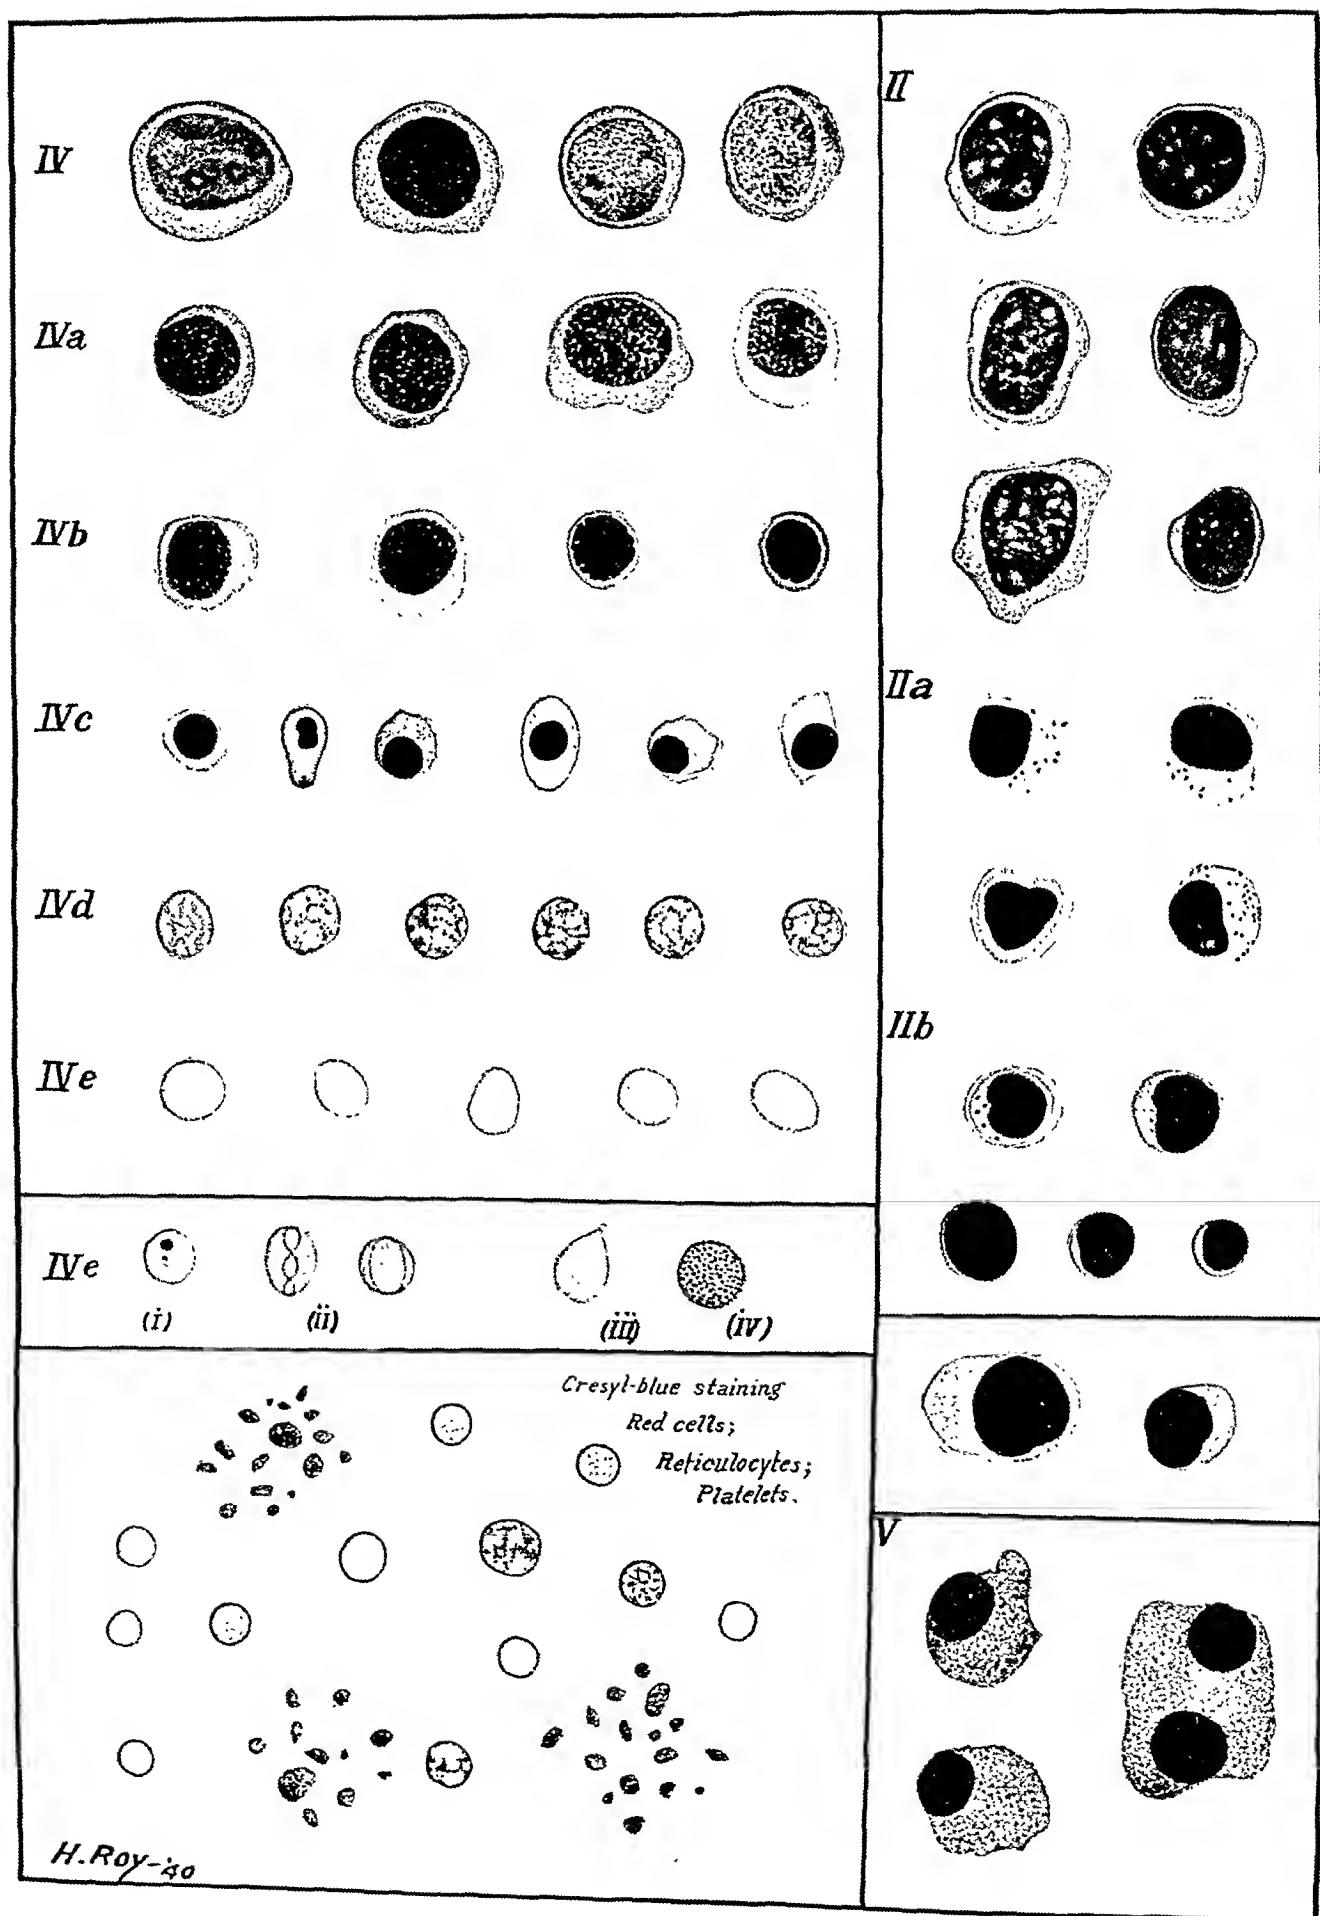

PLATE II

- IV. *Megaloblasts* (in the fourth cell the nucleus is much too red).
- IVa. *Erythroblasts*; in the fourth cell a considerable amount of haemoglobin has developed.
- IVb. *Macroblasts*; the second and third are well haemoglobinized; the last two are small varieties.
- IVc. *Normoblasts*; in the second cell the nucleus is dividing and about to be extruded.
- IVd. *Reticulocytes*.
- IVe. *Erythrocytes*: mature red cells.
 - (i) Red cell showing Howell-Jolly bodies.
 - (ii) Red cell showing Cabot's rings.
 - (iii) Missliapen red cell.
 - (iv) Red cell with basophilic stippling.
- II. *Lymphoblasts*.
- IIa. *Large lymphocytes* with azur particles.
- IIb. Mature (small) *lymphocytes*: the first with azur particles. Below the lymphocyte series are two *Turk's cells*; the characteristic cart-wheel structure of the nucleus is not very clear.
- V. *Plasma cells*.
Cresyl-blue supra-vital staining (see Part III).
Erythrocytes: *reticulocytes*: *platelets*.

Magnification about $\times 1,000$.

Staining—May-Grünwald and Giemsa, except figures in row IVd which are stained first with cresyl-blue and then Wright's stain [vide Part III, method A(b), i], and the block in the left lower corner in which all the cells are supra-vitally stained with cresyl-blue (vide Part III, method Bi).

PLATE II

is applied and the skin and subcutaneous tissues are pierced; a rotary movement will then facil-

is pierced and the marrow cavity is entered, there is a sensation of loss of resistance, just

tate puncture of the outer plate of the sternum (figure 4). As the external plate of the sternum

as is felt on entering the spinal canal during lumbar puncture. The stylet is now taken out,

the 2-c.cm. Record syringe is attached to the end of the needle, and the marrow blood is aspirated. When the fluid is aspirated the patient feels a dragging pain (figure 5) which is a guide as to whether the needle is in the marrow cavity or not. About 0.5 c.cm. of marrow (sinusoidal) blood is removed and the syringe and the sternal-puncture needle are withdrawn; digital pressure is applied over the puncture for a minute or two and the puncture is sealed with collodion. The needle is detached from the syringe and the latter is inverted several times so as to mix the contents thoroughly; then small drops are placed on clean slides and smears are made (*vide Part VI*). The rest of the fluid is put into an oxalate tube.

Only very rarely will one fail to obtain blood. The commonest error is to fail to allow a sufficient length of needle. In this case the guard must be adjusted slightly, the stylet replaced, and the needle pushed in a little deeper. Occasionally, the needle goes too deeply and has to be withdrawn slightly before blood will come. Our only complete failure was in a case of leucæmia, and in none of our cases of leucæmia has the blood come freely.

Not more than 0.5 c.cm. of blood is aspirated, because, if more is drawn, there is a probability that the negative pressure in the marrow cavity will draw blood from the vessels in the locality, and thus dilute the sinusoidal blood; it is probably impossible entirely to prevent this occurring, therefore a constant amount of blood is drawn to obviate gross differences in the degree of dilution in the samples taken from different persons. The syringe is inverted several times in order that the contents may be mixed thoroughly. This is necessary because the fluid that comes out at the beginning is not the same as regards cellular content as the fluid that comes out towards the end of the aspiration*.

Examination of material

(1) Examination of the stained smears :—

The sternal puncture smears are best stained with combined May-Grünwald and Giemsa staining which show the nuclear details very clearly. Failing this, satisfactory results for ordinary work may be obtained by staining with Leishman's or Wright's stain (*vide part VI*).

An accurate differential count of the different nucleated cells is made by counting 500 or more nucleated cells from different parts of a well-stained smear. The criteria on which the different cells are identified are given above.

(2) The oxalated specimen is examined for :—

- (a) enumeration of total nucleated cells (*vide Part II*),
- (b) estimation of haemoglobin (*vide Part I*),
- (c) enumeration of red cell (*vide Part II*), and

(d) estimation of reticulocyte percentage (*vide Part III*.)

Discussion

The material which is obtained by this procedure is neither peripheral blood (obviously) nor bone-marrow, but is blood from both the patent and the closed sinusoidal spaces in the haemopoietic tissue of the bone-marrow, in which are mixed a few cells detached from the walls of these sinuses by the intruding needle, or by the act of aspiration. The extent to which the detached tissue cells are added to the sinusoidal blood probably varies with each puncture and constitutes the weakness of the procedure from the point of view of obtaining a true and unvarying picture of bone-marrow haemopoietic activity. However, the extreme variations in a single subject that have been reported by some workers and the differences in the normals given by different workers can probably to some extent be accounted for by variations or defects in the technique employed, e.g., by the failure to remove a small and constant amount of blood, by failure to mix the blood before making smears, or by making counts from one part of the blood film only.

Zanaty (1937) has pointed out that wide variations may exist in the total nucleated-cell counts and that from these counts little idea of the activity of the bone marrow can be obtained, but from our experience of sternal puncture we believe that there is generally a distinct correlation between haemopoietic activity and the total nucleated cell count, though this may on occasions be misleading.

Both the haemoglobin and red cell count are slightly lower and reticulocyte count slightly higher in the sinusoidal blood than in the venous blood, but these estimations are of little practical value.

Normal standards

It is useful to know what proportions of the various cells one may expect to find in a sternal puncture. The data given by various writers are difficult to correlate, because they have adopted different methods of classification and different nomenclatures, and we prefer to quote only our own findings.

The data given in tables V and VI are from two sources :—

(a) First series : 10 normal individuals, males; 2 c.cm. of fluid taken.

(b) Second series : 53 subjects infected with filariasis; 0.5 c.cm. of fluid taken.

We have quoted the latter series because we believe that they represent the findings in normal individuals very closely, and because it is not easy to persuade 50 perfectly healthy individuals to undergo a sternal puncture. One might expect them to differ from the normal in the matter of the eosinophil cells, but in actual fact the percentage is lower than in the first normal series. The material differences that will be noted between the two series are almost

TABLE V
Sternal puncture : normal data

	FIRST SERIES		SECOND SERIES	
	Mean	Standard deviation	Mean	Standard deviation
Hemoglobin in grammes per 100 c.c.m.	13.43	± 0.93
Red cells per c.mm. in millions	4.99	± 0.40
Reticulocytes—percentage of red cells	0.75	± 0.39
Total nucleated cells per c.mm.	53,500	± 26,500	111,678	± 64,832
Nucleated red cells—percentage of total nucleated cells	25.75	± 4.07	27.606	± 11.746
Leucocytes—percentage of total nucleated cells	74.25	± 4.07
Granulococytes—percentage of total nucleated cells	64.40	± 5.10	54.529	± 11.421
Non-granular leucocytes—percentage of total leucocytes	9.85	± 2.43	17.889	± 6.796
Myeloid/nucleated-red-cell ratio	2.50	1.975

TABLE VI
Sternal puncture differential nucleated-cell count

	SERIES I		SERIES II		
	Range	Mean	Range	Mean	Standard deviation
Nucleated red cells .. Megaloblasts	0.0 to 1.5	0.7	0.0 to 3.25	0.92	± 0.7366
Erythroblasts	0.4 to 10.0	3.4	0.0 to 3.3	0.49	± 0.6619
Macroblasts	16.0 to 25.5	21.6	0.0 to 8.75	2.075	± 1.7675
Normoblasts	7.5 to 63.2	24.17	± 10.4505
White cell series .. Myeloblasts	0.4 to 1.5	1.2	0.0 to 0.75	0.15	± 0.2670
A. Granular series .. Pre-myelocytes	0.0 to 1.5	0.7	0.0 to 2.0	0.44	± 0.4409
Myelocytes—					
Neutrophil	1.0 to 9.5	4.4	1.0 to 18.75	8.30	± 3.2061
Eosinophil	0.4 to 2.6	1.3	0.0 to 4.0	1.445	± 0.9498
Basophil	None found.		None found.		
Meta-myelocyte-neutrophil	6.4 to 15.0	9.7	0.4 to 8.25	2.76	± 1.7257
Staff or band neutrophil	14.6 to 38.5	25.3	12.4 to 60.0	33.91	± 9.1938
Segmented neutrophil	6.5 to 25.6	16.8	0.0 to 23.6	5.35	± 5.0232
Mature eosinophils	0.0 to 7.6	4.7	0.0 to 7.4	2.77	± 1.6539
Basophils	0.0 to 1.0	0.2	0.0 to 1.2	0.08	± 0.2090
B. Non-granular series Lymphocytes	3.0 to 12.0	6.25	2.9 to 34.5	15.68	± 7.2623
Large mononuclears	1.2 to 7.0	3.0	0.0 to 3.5	1.585	± 0.9386
Plasma cells	0.0 to 1.6	0.6	0.0 to 1.25	0.31

certainly due mainly to the fact that in the second series we took a smaller amount of fluid and that there was consequently less dilution by systemic blood.

The main discrepancies are higher total nucleated cell count in the second series—higher than the 'normal' figure usually quoted, a lower myeloid/nucleated-red-cell ratio—also lower than the usual normal figure, a higher lymphocyte percentage, a higher staff neutrophil percentage with correspondingly lower percentages of both young forms and segmented neutrophils—which may be due to the personal factor, and a higher maximum figure for most of the cells—which may be due to the larger number of subjects involved in the second series : the 63.2 per cent for nucleated red cells can scarcely be classed as 'normal'.

For the findings of other workers reference should be made to Zanaty (*loc. cit.*), and Scott (1939).

Many writers claim that megaloblasts are not present in the normal sternal puncture material. This is a matter of nomenclature. The cell we have described as a megaloblast (*v. s.*) is seen in the normal marrow.

We seldom identify cells as lymphoblasts or monoblasts in cases of anaemia, but myeloblasts are occasionally found and appear in most of our counts, forming 0.1 to 0.2 per cent of the nucleated cells. In a properly-drawn and well-stained smear, there are very few 'disintegrating cells' and practically all the nucleated cells seen can be identified; in a highly active marrow, however, there are some cells which show mitotic division and are difficult to identify properly.

ORGANIZATION OF PUBLIC HEALTH AND MEDICAL SERVICES IN INDIA

By Sir R. N. CHOPRA, Kt., C.I.E., M.A., M.D.,
S.C.B. (Cantab.), F.R.C.P.

BREVET-COLONEL, I.M.S. (Retd.)

(Abstract from the Presidential Address, National Institute of Sciences of India)

THE Indian Empire, excluding Burma and Ceylon, extends from Persia and Afghanistan on the west to the borders of China on the east, and from about latitude 40° in the north to almost the equator in the south. This vast area, which presents a land of very varied contrasts in almost all respects, such as its physiography, climate, flora, fauna, anthropology, history, etc., came under the influence of European civilization at a relatively late date, but very material advances in almost all directions have resulted from this contact. Even in regard to this influence, however, the contrasts presented in different parts of the country bring out very vividly the vast nature of the extremely varied problems which had and have to be faced in the length and breadth of this great sub-continent.

Confining our remarks, as it is proposed in this communication, to the public health and medical services in this country, it is apparent that side by side with the most modern, up-to-date and efficient machinery such as is to be found to-day in any other part of the world, the state of affairs in many of the areas is almost as primitive as it was during the Moghul times or even earlier.

During the early times there was a relatively highly evolved system of curative medicine in vogue throughout the country. This was particularly well developed during the hey-day of Buddhism in the country, but the highly important preventive side was, as in almost all other countries during this period, non-existent. Contact with the West marked a material change, and one of the outstanding points of this change was that, with the exception of a relatively small number of private practitioners of the indigenous systems of medicine, the State assumed almost the entire responsibility for providing medical relief to the country. Hospitals, dispensaries and other adjuncts, together with the necessary personnel, were provided on a fairly liberal scale, but these were far from sufficient for the teeming millions of this great land. Further, in essentials all this provision concerned itself for a long time with the curative rather than the preventive side of medical relief. Within recent years in a few of the larger towns some public-spirited people or communities have also provided additional institutions of curative medicine, while the numbers of private practitioners have also materially increased. All the same, the present position is far from satisfactory, and, in view of the impending constitutional changes, it is proposed in this communication to take stock of the situation and suggest what should be done for improving the existing conditions.

Landmarks in public health administration in India

In the history of development of the Public Health Administration in India at least three landmarks have to be considered:

I. The appointment of a Royal Commission to enquire into the health of the army in India in 1859.

II. The report of the Plague Commission in 1904, following the outbreak of plague in 1896.

III. The Reforms introduced by the Government of India Act of 1919.

The Royal Commission of 1859 was appointed to enquire into the extremely unsatisfactory conditions of the health of the army in the country. Between 1859 and 1863, the mortality among European troops was 69 per 1,000, while among European women in 'married quarters' the death rate varied from 44 to 276 per 1,000. The Royal Commission recommended measures not only for the army but also for the civilian population. In accordance with its suggestions 'commissions of public health' were established in

Madras, Bombay and Bengal in 1864. The Commissions in Madras and Bengal advocated far-reaching measures, including the employment of trained public health staffs in the districts, but owing to various causes no definite policy was laid down. In the words of a former sanitary commissioner with the Government of India, 'Government had to deal with a population which was unwilling and unready to receive sanitation, which either frankly disbelieved in its efficacy and resented any change in established customs or was too ignorant and apathetic to understand the goal at which it aimed. Sanitary measures were received not only by indifference but by active opposition'. Under the circumstances, very little advance was possible, but the outbreak of plague in 1896 produced a profound effect which can best be summed up in the words of the sanitary commissioner at that time:

'When plague appeared it was not a new disease, but it was new to the present generation in Indians and it has exacted a very heavy toll of deaths all over the country. The strangeness of the disease, the unpopularity of the measures taken to control it and the importance of these measures have served to rouse the people from their apathy and concentrate the attention of all, but especially of the educated classes, on sanitation in a way that nothing else could have done.'

'At the same time plague has not been without its effect on Government. Previous to the advent of this disease it had been the generally accepted opinion that sanitation was the work of any medical officer and required no special training. A special sanitary staff had, therefore, not been considered of any very great importance. When plague appeared the staff was inadequate and unprepared; action was taken on general principles and sanitary measures were adopted, which, with further study of the aetiology, we now know were unsuitable and could do little to check the spread of the disease. The waste of life, time, money and effort that resulted has impressed on Government the necessity of being prepared in future and large changes have been effected with that object.'

The Plague Commission

The report of the Plague Commission in 1904 advocated the reconstruction of the sanitary department on a wide imperial basis, with the establishment of adequate laboratory accommodation for research, teaching and the production of sera and vaccines. The Indian Research Fund Association was formed in 1911 and a forward sanitary policy, with a devolution of powers to the local governments, was formulated in a resolution of the Government of India in 1914.

The Reforms of 1919 had a very marked effect on public health administration; this was partly beneficial and in other respects detrimental. Provincial ministers responsible to the legislature were anxious to hasten the growth of education, medical relief and sanitation so far as funds permitted. The organization of trained public health staffs for urban and rural areas, which the 'commissions of public health' had recommended in the sixties of the last century, was at last taken up in earnest and in the years succeeding the introduction of the Montague-Chelmsford Reforms, the organization of health services became a marked feature in most provinces. Since 1921 there has indeed been far greater public health activity in the provinces than ever before.

All civil medical services in the presidencies and provinces were formerly under the control of a single administrative officer known as the surgeon-general in the former and the inspector-general of civil hospitals in the latter. Unfortunately, owing to an insistent demand for medical relief, which is what appeals most to the individual in a community with a relatively low standard of living, the funds available were expended in the main on increasing and improving hospitals and dispensaries, and the obvious need for more and yet more of these, associated with a chronic shortage of funds led to the neglect of preventive measures, and particularly of those fundamental but costly ones comprised in the term 'environmental hygiene'.

Relief of sickness and suffering was readily understood and appreciated by the public, while the application of sanitary measures, implying as it did interference in age-long habits, with restrictions which were regarded as irksome and trespassing upon vested interests or religious customs, was opposed on all hands by the people who are as conservative as any in the world. *En passant* it may be noted that the position in India at this time was generally very similar to that in England some hundred years ago.

Separation of preventive and curative departments

Early in the present century the Secretary of State for India caused the separation of preventive from curative medicine by creating in each presidency and province a separate 'department' for preventive medicine, with an independent budget, and under an officer designated as the 'sanitary commissioner'; the name of the officer was changed in 1922 to the less appropriate one of 'director of public health', and his department was also designated as the 'public health department'. In many provinces the division of duties as between the heads of the departments of curative and preventive medicine was not fully specified, only a broad distinction of curative and preventive medicine being regarded as sufficient. The formation of separate departments for preventive medicine in the various provinces provided a great impetus for this branch of medical work, and far-reaching much-needed reforms were planned. These in many cases were well advanced when the great war (1914-19) called a halt for the time being. After the war the young public health departments again got busy. They found themselves faced with the immense problem of environmental hygiene in a land where, even in towns, safe water supply and sanitary systems of sewage and rubbish disposal were, as a rule, conspicuous by their absence, the housing of the poorer classes was atrocious, and local administration, except in a few outstanding cases, was over-shadowed by vested interests and correspondingly inefficient. In the rural areas, sanitation simply did not exist, soil pollution was general, flies swarmed, malaria and hookworm infection were almost universal, leprosy and tuberculosis were widespread and smallpox, cholera and plague regularly took their periodic tolls uncontrolled by any environmental checks or preventive measures. The provision of properly qualified and trained staff for this work presented a further difficulty. The medical department had its system of hospitals and dispensaries manned by civil surgeons, assistant surgeons, and sub-assistant surgeons. In some provinces the civil surgeons, originally ex-officio district medical and sanitary officers, retained the dual charge, while the public health department was building up a subordinate personnel of sanitary inspectors, epidemic sub-assistant surgeons or 'health assistants' to civil surgeons and later health visitors. All these worked under the director of public health who had one or more assistant directors and other specialists, leaving the provision of the more costly full-time district health officers, until the subordinate personnel had been trained and appointed. Other provinces hastily appointed expensive district sanitary officers, whom in some cases they called medical officers of health, although, owing to the fact that every district already had a district medical officer or the 'civil surgeon' as he is usually called throughout India, their duties were not comparable with those of medical officers of health in England. Further, in the absence of a separate staff of subordinates the work of these new officers was limited to advising. As an exception, the Presidency of Madras succeeded in creating a complete staff of health officers, assistant officers, and sanitary inspectors.

*Lack of co-operation between medical and public health departments**

The question at the present time is the lack of a co-operation and consequently of co-ordination obtaining

* Jolly, G. G. The need for co-operation in the Medical Health Services of India, with special reference to Maternity and Child Welfare, *I. M. G.*, April 1940.

in many parts of India between the official medical and public health departments. This is a problem peculiar to India for it does not exist in western countries, nor in the dominions and colonies where the separation of the official health services into 'curative' and 'preventive' has never been effected. To some extent this is due to the unsuitable titles given to the respective departments and still more to their administrative heads. In the presidencies the head of the medical department, as has been remarked already, is known as the 'surgeon-general', a passable application with an historical basis as it is applied to the chief of the United States public health service. In the provinces on the other hand the head of the medical services is known as the 'inspector-general of civil hospitals', an inadequate and misleading designation for one who is the adviser to Government on all matters connected with medical relief, administrator of all public medical institutions, head of the medical services in the province, president of the provincial medical council of registration and medical education and president or chairman of a host of other medical organizations and committees. The designation 'director of public health' is equally inappropriate, since it implies an impossible power and a range of activities much wider than are possible under existing conditions. The two titles together are largely responsible for the confusion of functions pertaining to the two departments and the consequent overlapping, duplication and wastage of their resources. Another factor contributing to this confusion has been the absence of orders laying down the exact policy and scope of work for each department.

It has been asserted that the maintenance of separate departments for medical relief and preventive medicine is an advance upon the English system. Its advocates point out that it enables experts on each side to administer their own subjects. While the specialists in preventive medicine argue that those who have not taken a diploma in public health cannot appreciate the requirements and scope of their work, the clinicians hold that public health personnel is so fully occupied with environmental hygiene that it loses all touch with clinical work and is, therefore, not the proper agency for the administration of medical relief. There is much to be said on both sides. Even in England similar views have been expressed by recognized leaders of the profession. But in actual practice the maintenance of two separate public medical services has not led to satisfactory results in India. So long as the public health department limited its activities to environmental hygiene there was little or no difficulty. This subject offers so vast a field that it could well keep a large department fully occupied for many decades to come. As soon, however, as the separate public health department proceeded to interest itself in individuals rather than communities, overlapping began to appear; this has been most marked in the fields of maternity and child welfare, leprosy and tuberculosis, and even rural medical relief. In regard to midwifery a tendency appears to be developing which, if it is not checked, may lead to a conflict between practising doctors and health visitors and midwives. Already with the peculiar social conditions prevailing in this country medical colleges and schools are finding it increasingly difficult to obtain the requisite number of 'cases' for training. The position in regard to such diseases as leprosy and tuberculosis is anomalous. In one province the inspector-general of civil hospitals is responsible for leprosy work, in another the director of public health. The same applies to tuberculosis.

There is evidence, where it occurs, of a lack of co-operation between the two official departments and of the development of 'exclusion' instead of an *esprit de corps* which can only be destructive in its effects. The situation requires to be met by a close liaison between the two branches, such as, for example, obtains in the Government of India, where the director-general, Indian Medical Service, has the public health commissioner working with him in his office as his principal staff colleague. Such an arrangement not only conduces to a close co-operation, but the distribution of work

is facilitated. The urgent necessity for a friendly collaboration between the two departments, if the system is not to break down, is essential, and is recognized by experienced administrative officers of both departments. The Central Advisory Board of Health, established in 1937, should prove a valuable agency in this direction. At its meeting in Madras in January 1939, it passed the following resolution for the establishment of similar provincial boards of health:

'The Board stresses the desirability of establishing in each province and state an advisory board of health with the Minister-in-charge as chairman.'

While in reference to maternity and child welfare it adopted the following resolution:—

'Co-ordination between the medical and public health departments is perhaps more vital in the field of maternity and child welfare than in any other of medical and public health work.'

If a policy of close friendly collaboration obtains between the two departments in the provinces and the relative spheres of each are defined, the existing system will continue to function tolerably well, but, if friendly co-operation that should be sought and loyally observed by colleagues in both the departments, is replaced by a spirit of exclusion, and co-operation is stigmatized as a 'dual control', then the position in which the two departments are in opposition will arise sooner or later and the profession will be divided into two camps. Such a state of affairs will hardly be in the interest of either of the two departments, while the effects of such a controversy is bound to lead to a great deal of suffering for the poor public.

Federal ministry of health

The best solution of the problem would be the establishment of ministries of health in various provinces modelled on the English system with suitable modifications in regard to the local conditions.

Public health service in Great Britain

The modern public health service in England is barely a quarter of a century old and, like so many of the English institutions, it arose more by accident than by design. The dissolution of the monasteries left the destitute without visible means of support until the year 1601 when the Elizabethan Poor Law established parish overseers and workhouses—this system remained practically unchanged for over two centuries. Besides relieving destitution, these authorities carried out any measure that was necessary for the public health, such as the control of epidemics, the provision of sewers, or the abatement of sanitary nuisances. In 1834 the Poor Law Amendment Act was passed after a great deal of agitation and following the Report of the Poor Law Commission of 1832. This important bill amalgamated the separate parishes into unions under the control of boards of guardians. District medical officers were appointed to attend to the sick poor, while the infirmaries were built to accommodate paupers who were too ill to remain in the workhouses. In 1855 the Municipal Corporations Act was placed on the statute book to reform the chaotic state of borough government.

Despite all these changes, the state of the public health was never taken very seriously until the cholera epidemics between 1830 and 1854 galvanized the Government into action. Edwin Chadwick, one of the Poor Law commissioners, in his *Survey into the Sanitary Condition of the Labouring Classes of Great Britain*, exposed, not only the insanitary evils of the towns and villages, the hideous legacy of the industrial revolution, but, by showing how closely disease was related to poverty, provided convincing argument in favour of far-reaching reforms. His 'sanitary idea' led to the appointment in 1848 of the General Board of Health, which, after a stormy life, was superseded by the Local Government Board of 1871. In 1872 the country was divided into urban and sanitary districts, and medical officers of health and inspectors of nuisances were appointed for the first time. Credit is due to the authorities of the Liverpool Borough for having had

the vision to appoint a medical officer of health as early as 1847. Then followed the great Public Health Act of 1875 which is the bulwark of all sanitary laws.

A further Municipal Corporation Act was passed in 1882, while the year 1888 was conspicuous for the creation of county councils and county borough councils. From this time onwards there has been an ever-widening stream of health legislation. Statute after statute has swollen the ranks of the public health service to such an extent that to-day there is scarcely any field of human activity in which the health officer does not play a part. Another important landmark, the National Health Insurance Act of 1911, provided the adult manual worker with compulsory insurance against loss of health. The Bill was hotly contested during its passage through Parliament, but it was successfully piloted and passed into law through the efforts of Mr. Lloyd George.

Finally, the creation of a Ministry of Health in 1919 out of the stones of the Local Government Board was the crowning recognition of the importance of health in the nation's life. This wise step was made inevitable by the Great War of 1914-18.

Ministry of health

The general powers and duties of the Minister in relation to health are defined in the second clause of the *Ministry of Health Act*, 1919, as follows: 'To take all such steps as may be desirable to secure the preparation, effective carrying out and co-ordination of measures conducive to the health of the people, including measures for the prevention and cure of diseases, the avoidance of fraud in connection with alleged remedies therefor, the treatment of physical and mental defects, the treatment and care of the blind, the initiation and direction of research, the collection, preparation, publication and dissemination of information and statistics relating thereto, and the training of persons for health services.'

The Ministry of Health is the chief tribunal for local authorities. Broadly, it engages in the following activities:—

- (1) Public health.
- (2) Local government and local finance.
- (3) Housing and town planning.
- (4) Poor Law administration.
- (5) National health insurance.

'Power', wrote J. S. Mill, 'may be localized, but knowledge to be most useful must be centralized'. Thus, while most executive functions are passed over to the local authorities, the Ministry seeks to maintain proper standards of efficiency amongst them. It supervises their methods of government, especially in regard to the public health matters. Certain too-forward authorities have to be restrained, while other backward ones have to be spurred on to better achievement. One of its most important functions is the control of local expenditure by sanctioning loans only after careful inquiry.

The medical department, under the chief medical officer, is divided up into the following sections:—

- (1) Medical intelligence, infectious diseases, international health, etc.
- (2) Maternity and child welfare.
- (3) Tuberculosis, venereal disease and institutional therapy.
- (4) Nutrition, food and drugs administration, London hospitals, water supplies, etc.
- (5) General practitioner services and insurance.
- (6) Surveys, hospitals, environmental hygiene, and public assistance.
- (7) Medical services, emergency hospital.
- (8) Welsh Board of Health.

Each of these divisions is in charge of a senior medical officer who is responsible to the chief medical officer for the work carried on in his division. Furthermore, regional medical officers are employed to supervise the work of the panel doctors and the pharmaceutical chemists under the National Health Insurance scheme, while other officers are detailed to

HEADACHE IS DISABLING

Headache may be as disabling as a grave illness. In migraine particularly, the headache is of all degrees of intensity, at times so severe as completely to incapacitate the sufferer. It is noteworthy how quickly the patient can obtain relief with Veganin. Composed of minimum doses of acetylsalicylic acid, phenacetin and codeine, Veganin affords striking proof of the superior analgesic potency of this synergistic alliance over that of its components administered separately. Recurrent painful conditions, such as migraine and dysmenorrhœa, yield with impressive promptness to the efficacy of Veganin.

VEGANIN TABLETS

Supplied in tubes of 10 and 20. Veganin is not advertised to the public.

A trial supply to Physicians on request.

INDIAN MEDICAL PUBLICATIONS

ACTON.—On the Dysenteries of India, with a Chapter on Sprue. By Lieut.-Col. H. W. Acton, I.M.S., and Lieut.-Col. R. Knowles, I.M.S. With charts and illustrations in black and white and 5 coloured plates. Rs. 7-8.

ANDERSON.—Hints to Dressers. By Lieut.-Col. S. Anderson, M.B., B.Sc., C.M. (Glas.), I.M.S. Second edition, enlarged. Rs. 2.

BIRCH'S Management and Medical Treatment of Children in India. Eighth edition. Thoroughly revised and largely re-written. By Lieut.-Col. E. H. Vere Hodge, B.A., M.D. (Cantab.), F.R.C.P. (Lond.), I.M.S. Rs. 7-8.

BIRDWOOD.—Clinical Methods for Students in Tropical Medicine. A guide for students and general practitioners in the tropics in diagnostic and therapeutic measures. By Lieut.-Col. G. T. Birdwood, M.A., M.D., D.P.H., I.M.S., Late Principal, Medical School, Agra. Fourth edition. Rs. 6.

BIRDWOOD.—Practical Bazar Medicines. With over 200 useful prescriptions. By Lieut.-Col. G. T. Birdwood, M.A., M.D., I.M.S. Third edition, interleaved. Rs. 3-8.

BOSE.—A Handbook of Diabetes Mellitus and Its Modern Treatment. By J. P. Bose, M.B. (Cal.), Diabetes Research Department, Calcutta School of Tropical Medicine. Third edition, revised and enlarged. Rs. 7-8.

CASTOR.—A Short Guide to the Instruments and Appliances required for Operations and the Dressing of Cases. By Lieut.-Col. R. H. Castor, I.M.S. Second edition. Revised by Lieut.-Col. F. P. Connor, I.M.S. Re. 1.

COVELL.—Malaria Control by Anti-Mosquito Measures. By Colonel Gordon Covell, M.D. (Lond.), D.P.H., D.T.M. & H. (Eng.), I.M.S., Director, Malaria Institute of India. With 13 text-figures and 2 plates. Second edition, enlarged and brought up to date. Rs. 7-8.

CRAWFORD.—A History of the Indian Medical Service, 1600—1913. By Lieut.-Col. D. G. Crawford, B.M.S. (Retired List). Royal 8vo. Two volumes. Cloth Gilt. Rs. 15.

CRAWFORD.—Roll of the Indian Medical Service, 1615—1930. By Lieut.-Col. D. G. Crawford, B.M.S. (Retd.). Rs. 20.

DAS.—A Textbook on Midwifery for Medical Schools and Colleges in India. By Kedar Nath Das, C.I.E., M.D. With 280 illustrations. Royal 8vo. Rs. 8.

DEY.—The Indigenous Drugs of India. Short descriptive notices of the principal medicinal products met with in British India. By Kanny Lali Dey, C.I.E. Second edition. Rs. 6.

DUTTON.—Case-Taking Medical and Surgical for Students. By Lieut.-Col. H. R. Dutton, I.M.S., M.R.C.P. (Lond.), D.T.M. & H. (Camb.), M.R.C.S. (Eng.), Superintendent, Temple Medical School, Patna. As. 12.

GREEN-ARMYTAGE.—Tropical Gynaecology: Selected Essays. By Lieut.-Col. V. B. Green-Armystage, M.D., I.M.S. F'cap 8vo. Rs. 3-8.

INDIAN JOURNAL OF MEDICAL RESEARCH. Published under the authority of the Indian Research Fund Association, Simla. Quarterly in January, April, July, October. Subscription (including Special Memoirs), Rs. 16; post free. Payable in advance.

INDIAN MEDICAL RESEARCH MEMOIRS. Supplementary Series to the Indian Journal of Medical Research. Supplied free to the subscribers of the Journal. List on application.

KEITH-THOMPSON.—A Practical Guide to the Edinburgh F.R.C.S. For Doctors from Abroad. By Mary Keith-Thompson, M.A., M.B. (Cal.), F.R.C.S. (Edin.), D.T.M. & H. (Eng.), L.M. (Dub.). Rs. 2.

KNOWLES.—Malaria: Its Investigation and Control with Special Reference to India. Including a short chapter on treatment conditions. By Lieut.-Col. R. Knowles, I.M.S., and R. Senior White, Malaria Research Officer, Central Malaria Bureau, Government of India. Rs. 5.

KNOWLES.—The Poisonous Snakes of India. Illustrated after Fayrer, Acton and Wall. A chart for the identification of the common species of poisonous Indian snakes and for the treatment of snake-bite. With 15 illustrations, ten of which are in colour. Unmounted. Rs. 3-8. Mounted on linen and rollers and varnished. Rs. 8. In book form on linen. Rs. 5.

KNOWLES.—The Treatment of Intestinal Amoebiasis. An analysis of results and a review of the literature from the Department of Protozoology, Calcutta School of Tropical Medicine. Re. 1-8.

LUKIS.—An Elementary Manual of Midwifery for the Use of Indian Midwives in Receipt of Scholarships from the Victoria Memorial Scholarship Fund. By Surgeon-General Sir Pardsey Lukis, M.D., F.R.C.S., K.C.S.I. Third edition. Re. 1.

LUKIS AND BLACKHAM.—Tropical Hygiene for Residents in Tropical and Sub-Tropical Climates. By the Hon. Surgeon-General G. P. Lukis, C.S.I., I.M.S., and Major R. J. Blackham, R.A.M.C. Fourth edition. Revised by Lieut.-Col. A. D. Stewart, M.B., D.P.H., I.M.S. Rs. 5.

LYON'S Medical Jurisprudence for India. With illustrative cases. By Lieut.-Col. T. F. Owens, F.R.C.P.S., I.M.S. (Retd.). Ninth edition. Rs. 15.

MAYNARD.—Manual of Ophthalmic Operations. By Lieut.-Col. F. P. Maynard, M.B. (Durh.), D.P.H. (Canlab.), F.R.C.S. (Eng.). Second edition. With six stereoscopic plates and 137 illustrations. Rs. 4.

MAYNARD.—Manual of Ophthalmic Practice. Based on lectures delivered at the Medical College, Calcutta. By Lieut.-Col. F. P. Maynard, M.B., D.P.H., F.R.C.S. With 12 plates and 133 illustrations. Rs. 4.

MCWATTERS.—The Principles of Surgical Dressing. An introduction to practical surgery. By Lieut.-Col. R. G. McWatters, M.B., F.R.C.S. Rs. 2-8.

MEDICAL CHARTS. Nos. 1, 3, 7, 10, 11, 16 and 17. List on application.

MENON.—An Introduction to Tropical Pathology. By T. Bhaskara Menon, M.D., M.R.C.P. Rs. 10.

NEWMAN.—Irrigation in Cataract Extraction. By Lieut.-Col. E. A. R. Newman, C.I.E., M.D., B.Ch. (Cantab.), M.R.C.S. (Eng.), L.R.C.P. (Lond.), I.M.S. Rs. 2.

OVERBECK-WRIGHT.—Mental Derangements in India: Their Symptoms and Treatment. By Captain A. W. Overbeck-Wright, M.B., Ch.B., D.P.H., I.M.S. Rs. 3.

JOURNAL OF THE MALARIA INSTITUTE OF INDIA. Published under the authority of the Indian Research Fund Association, Simla. Half-yearly in English. Edited by the Director, Malaria Institute of India, Kasauli. Subscription in India Rs. 7-8, for 4 numbers, post free. Single copy Rs. 3, postage extra.

SMALL.—Anglo-Urdu Medical Handbook: Or, Hindustani Guide for the Use of Medical Practitioners (Male and Female) in Northern India. By Rev. George Small, M.A. Rs. 2.

STALEY.—Handbook for Wives and Mothers in India and the Tropics. Including chapters on the Care of Children. By Dr. Mildred Staley. Rs. 4.

STRICKLAND.—A Short Key to Both Sexes of the Anopheline Species of India, Ceylon and Malaya. By C. Strickland, M.A., B.Ch. (Cantab.), Professor of Medical Entomology in the School of Tropical Medicine, Calcutta. Re. 1-12.

STRICKLAND.—Mosquito Factor in the Malaria of Assam Tea Gardens. By C. Strickland, M.A., B.Ch. (Cantab.). As. 8.

STRICKLAND AND CHOUDHURY.—An Illustrated Key to the Identification of the Anopheline Larvae of India, Ceylon and Malaya. With practical notes on their collection. By C. Strickland, M.A., B.Ch. (Cantab.), and K. L. Choudhury, M.B., D.P.H. (Cal.). With Supplement, Rs. 6. Supplement separately, Re. 1-12.

investigate serious epidemics of infectious diseases, outbreaks of food-poisoning, or make surveys of local government areas. These surveys are extremely valuable. Not only do they provide comparative indices to enable the Ministry to issue reports, circulars, and memoranda for the information and guidance of local authorities, but, incidentally, they help the medical officer of health to overcome some of the more difficult problems of administration.

Proposed Federal Ministry of Health of the Government of India

In India, a Federal Ministry of Health should be established at the centre to provide the necessary co-operation agency for the provincial local self-government departments, which are at present responsible for the supervision of local bodies and for public health administration in the provinces. This Ministry would also be responsible for the other health functions statutorily conferred on the Central Government by the Government of India Act of 1935. All problems in connection with curative and preventive medicine should be dealt with by one department which should be divided into appropriate sections. The following sections are tentatively suggested for consideration:—

- (1) Prison medical service.
- (2) Port sanitation and quarantine service.
- (3) School medical service.
- (4) Public health including—
 - (a) Medical intelligence, infectious diseases and international health.
 - (b) Nutrition, food and drugs administration including biological products.
 - (c) Environmental hygiene, including housing, water supply, drainage, disposal of waste products.
 - (d) Industrial hygiene.
- (5) Medical relief including—
 - (a) Maternity and child welfare, venereal diseases, tuberculosis, leprosy.
 - (b) General practitioner services with special regard to rural dispensaries.
 - (c) Hospitals.
 - (d) Drug addiction.
 - (e) Health insurance.
- (6) Lunacy.
- (7) Scientific research.

For these purposes, the Ministry should have a highly-trained staff of expert advisors. The director-general, Indian Medical Service, who as surgeon-general with the Government of India most nearly corresponds to the chief medical officer of the Ministry of Health in England, has at present an insignificant number of specialists on his staff. In England though public health administration is established on well-regulated lines, the chief medical officer controls a strong team of workers in each special subject of medical health work, such as maternity and child welfare, tuberculosis, industrial hygiene and so on. In India on the other hand while the conditions are much more complex, and although the necessity for an expansion of the Central Government's technical staff has been repeatedly stressed by the director-general and public health commissioners, the task is left to only two or three officers.

Materials available

The materials for the establishment of a Ministry of Health at the centre in India are all available. Thus, though many of the bureaux are under private bodies, their directors act as advisers to the director-general who, as a rule, is connected with such bodies as the chairman of their managing committees. Thus, with the director-general at the top we have roughly:—

- (1) Public health commissioner—Bureau of quarantine, infectious diseases and international health.
- (2) Deputy director-general—Personnel and establishment, medical relief, medical education, etc.
- (3) Assistant director-general (stores)—Medical supplies.

- (4) Maternity and child welfare bureau of the Indian Red Cross Society, with the director-general as its chairman.
- (5) Medical commissioner, Tuberculosis Association of India.
The director-general is its chairman.
- (6) Medical research.
The director-general is head of the medical research department and chairman of the Scientific Advisory Board, Indian Research Fund Association, and the public health commission its secretary.
- (7) Drugs control.
The director-general has the director of drug control laboratories on his staff and is also the chairman of the advisory board for drug control.
- (8) Nutrition.
The Director of Nutrition Research Institute, the officer in charge of the Nutrition Enquiries of the Indian Research Fund Association, acts as the expert adviser to the director-general.
- (9) Malaria.
The Director of the Malaria Institute of India acts as the adviser to the director-general.

Other loose connections exist or are being forged, e.g., leprosy through B.E.L.R.A.; food standards through a standing committee to be set up by the Advisory Board of Health, while new connections have to be established with the railway medical services and prison medical services, school medical services, etc.

The provision of a suitable staff of experts must devolve on the Federal Government and cannot be relegated to the provinces. The Royal Commission on Health in Australia (1925) emphasized that, as 'the success of health administration is more dependent on the personality and capability of the officers directing it than on any other single factor, the Commonwealth Government should be responsible for the maintenance of highly trained experts to advise and help local authorities when desired by State Health Administrations'. If such an arrangement suits Australia, I agree with Raja (1937) that a similar plan might be equally successful in India. Moreover, a carefully selected central staff would, to some extent, avoid the duplication of posts of highly specialized men in the component States of the Federation, and the position and prestige of the Federal administration should enable it to attract the proper type of men.*

The selection of the Federal chief medical officer should be dependent on his being both medical and public health experience, and deputies must be given a chance to familiarize themselves with the wide range of the curative, preventive and constructive aspects of medicine.

Public health organization in the Provinces

Each province should have a chief medical officer responsible to the Minister of Health of the province for the administration of the whole of the medical subject with a number of deputies in charge of the various departments, e.g., prisons, schools, medical and public health problems. The deputies should be given a chance to work in different departments, so that the chief medical officer of the future would have men available with first-hand experience of individual and environmental hygiene, while regional medical officers should be appointed to look after various areas or zones.

A provincial board of health under the chairmanship of the Minister of Health should be constituted in each province. The members should be drawn from the medical and public health specialists and suitable persons should be co-opted for different problems. The help of the revenue, education and public works departments would be needed to shape the health

* Raja, K. C. K. E. 'A plea for a forward Public Health Policy in India'. *Indian Med. Gaz.*, 1937, Vol. LXXII, p. 428.

policy of the province. Suitable persons may be constituted into *ad hoc* committees to tackle important problems of general and local interest, while the co-operation and advice of the specialists on the staff of the Federal Ministry of Health should be available to the provincial governments in connection with problems of an all-India nature.

In the districts, district health committees should be formed for the same purpose. These should be presided over by the collector of the district or the president of the district board; the co-operation of both agencies is essential, and this alone will make it possible for these committees to work efficiently.

So far as the rural population is concerned, medical men engaged in curative work should be able to undertake public health duties as well. Their education and training should be of such a nature as to enable them to do so without difficulty. The doctors engaged in combating epidemic diseases should be expected to undertake public health work when not dealing with outbreaks of infectious diseases. The rural doctor, who is the final link between the health services in this country and the people, can also impart elementary health education to patients in connection with immediate surroundings. Such instruction would be much more effective than general lectures and demonstrations to large audiences.

Conclusions

To sum up the views expressed above, I consider that, under the conditions prevailing in India at present, the State is essentially responsible for preventive and curative medicine. Curative medicine forms an integral part of the public health services of a country inasmuch as very often the sick man is the source of infection and no constructive medicine is possible unless the population is rendered free from disease by treating the individuals. Again according to the newer conceptions of a State, it is necessary that disablement whether temporary or permanent should be cut down to the barest minimum through intensive use of curative medicine. Moreover, it is through curative medicine alone that it is possible to win the confidence of the public in a country like India

and bring home to people the advantage accruing both from preventive and constructive medicine.

Starting from the bottom, I consider that to meet the requirements of public health of the population there should be combined establishment which should form the basis of preventive, curative and constructive medicine in each village. This should be linked up with a more organized central agency discharging these combined duties and catering for a convenient sized population, the bulk of which will depend upon various factors, such as communications, incidence of disease, etc. These primary organized centres will be supervised and assisted by a district centre in which there should be a specialized staff for the main medical subjects. These district centres in turn should be in touch with a larger provincial organization in which the staff consisting of specialists in various branches of medical science should work under a senior and experienced medical man. This latter should constitute the administrative head of the medical service in the province under the provincial Ministry of Public Health. He should have a thorough training in the methods of public health administration, community health organization, constructive medicine, etc. The staff of the provincial organization should further be large enough to be utilized for medical and public health training, both undergraduate and post-graduate.

The activities of the health organization in different provinces should be co-ordinated by a more elaborate and efficient Federal, or all-India, organization working under the Federal Ministry of Health. The administrative head should be an officer with wide experience of preventive, curative and constructive medicine, and have on his staff expert advisers in as many of the important branches of medicine as possible. With the advice and help of these advisers, it should be his duty to deal with and co-ordinate the problems of public health which concern the country as a whole. Curative and preventive medicine must work as one single whole; to let them work separately in watertight compartments is sure to lead to confusion, while only an organization of the nature detailed above will be able to deal successfully with the multifarious problems of public health in this vast country.

Medical News

TUBERCULOSIS WORKERS' CONFERENCE

The second Tuberculosis Workers' Conference was held in New Delhi from November 18th to 21st and was attended by about 90 delegates including workers from tuberculosis institutions, representatives from public health departments of Provinces and States, of local government authorities, of the army and of the railway.

The first morning of the conference was presided over by Her Excellency the Marchioness of Linlithgow, President of the Tuberculosis Association of India. In requesting Her Excellency to open the conference, General Jolly, chairman of the Association, spoke of the personal interest and the detailed attention which Her Excellency paid to all the affairs of the Association matched by an equally detailed knowledge of the subject and of the various administrative difficulties that had to be faced in an organized effort to combat the disease. He knew that he was expressing the feelings of every tuberculosis worker throughout India, whether lay or medical, when he said that they were filled with gladness at the thought that circumstances had made it possible for Her Excellency to remain with them another year and that they would continue to enjoy her inspiration and guidance for that period.

Lady Linlithgow, in opening the conference, said:

'Once again I have the pleasure of welcoming you to a conference of tuberculosis workers. The value of the last one held just a year ago is convinced by the recently published report. The advocacy of the

different treatments by various eminent doctors, the results obtained, the statistics kept, all tend to throw light on the treatment of the disease and to determine the effect of climatic influences in conjunction with treatment.

The very necessary subject of tuberculosis surveys has been examined by a sub-committee of the Indian Research Fund Association under General Jolly and they have drawn up a comprehensive report which is to be discussed. This gives me great satisfaction, as without surveys it seems to me impossible to get a true picture of the situation, and conjecture is most unsatisfactory when dealing with a problem of this magnitude.

We shall have the great pleasure of showing you the Model Clinic in Delhi which was started after the conference last year and which is almost completed. This has fulfilled one of my dreams.

Another will shortly be fulfilled in the form of the Kasauli Sanatorium and Teaching School. The Government of India have generously made this possible by granting the necessary expenditure subject to ratification by the Assembly. Some of you may remember that I spoke last year about the possibility of constructing an institution in the Simla Hills embracing a sanatorium with facilities for training. That institution will now be available. To those of you who do not know, I would like to tell of the Pasteur Institute's generosity. They offered me their buildings and property and accompanied that offer with a suggestion of an annual

grant which we hope will materialize. A certain amount of reconstruction will have to be undertaken and roads must be improved. Plans are now being drawn up and we hope to put the work in hand very shortly. Provision for a hundred beds is being made with room for expansion and we hope that support will come from all parts of India as we wish it to be an all-India institution. According to the amount given, beds will be reserved for that province or state, and doctors can come from any part of India for training. I do earnestly ask any of you who may come to hear of plans for constructing small buildings with money which is not adequate for the purpose, to turn their attention to an annual grant for Kasauli, with a corresponding number of beds.

You will I know be interested in Doctor Frimodt-Möller's sub-committee's report on the classification of pulmonary tuberculosis which is to be presented to the conference.

A special feature of the discussions this year is on the subject of environment in relation to tuberculosis, an aspect which so far has received very little attention and which is of such great importance. I hope very much that the whole conference will benefit from a frank discussion and that the outcome will be a deeper knowledge of the necessity of suitable environment for successful treatment of the disease.

After the opening function the conference was in session for four days, during which eleven papers were read, each followed by a full discussion.

[A short résumé of the papers and the discussion were received too late for inclusion in the present number. They will appear in the February number.]

MEDICAL STORES SUPPLIES IN INDIA

MANY problems affecting medical supplies to the Army were considered at the third meeting of the Drugs Supplies Committee, now called the Medical Stores Supplies Committee, held recently under the chairmanship of Lieut-General G. G. Jolly, I.M.S., Director-General, Indian Medical Service.

Samples were shown of emetine hydrochloride, apomorphine hydrochloride, acriflavine and dried blood plasma made in India under schemes of investigation fostered by this committee in close liaison with the Board of Scientific and Industrial Research of the Commerce Department.

To combat shock through loss of blood, blood transfusion is largely used in modern medicine. Such blood is difficult to obtain in quantity for the treatment of the wounded in the field and other methods are being carefully considered. One of the most successful and promising of these methods is the use of dried blood plasma. Blood to which sodium citrate has been added to prevent coagulation is allowed to settle and the clear liquid drained off. This liquid is dried *in vacuo* to a granular powder and packed aseptically in containers. Before use it is made into a solution with sterile water and given to the patient in the same manner as a blood transfusion. A sample of dried blood plasma, the first to be made in India, was shown to the committee which discussed the question of its manufacture in India.

The production of emetine hydrochloride which is still required for the treatment of amoebic dysentery is dependent upon the growth of ipecacuanha. This drug grows wild in the forests of South America but is more and more difficult to obtain the further the forests have to be penetrated. Ipecacuanha however has been demonstrated to grow well in Mungpoo, Bengal, and the question of encouraging its cultivation in India is under consideration.

Much progress has recently been made in Travancore, Bombay and Madras in the development of fish-liver oil schemes for supplying India with substitutes for cod-liver oil. The essential factor in these oils is their content of vitamin A and vitamin D. As the shark-liver oil has ten times the vitamin A content of cod-liver oil it forms a valuable source of vitamin A. This oil however is lacking in vitamin D so that it is necessary

to add this vitamin to it. Vitamin D, a complex chemical substance, has now for the first time been made in India at the Indian Institute of Science.

PROGRESS OF INDIGENOUS MANUFACTURE

OWING to the extended production of drugs in India as many as 92 various drugs have been taken off the import list.

The manufacture in India of suitable disinfectants has been taken up by the Medical Stores Supplies Committee under the chairmanship of Lieut-General G. G. Jolly, I.M.S., Director-General, Indian Medical Service. Attempts are being made to produce a complex chlorine compound hitherto imported which is essential for the manufacture of many non-irritating efficient disinfectants which are now so largely used. Acriflavine is also an important disinfectant, particularly in war time, and its manufacture in India from locally produced materials is under investigation. Samples have already been produced in an Indian laboratory.

Troops in the field deprived of fresh fruit or vegetables develop scurvy. To prevent this disease, tablets of vitamin C are made up and India's most concentrated form of vitamin C is 'amla'. Amla berries are collected in the Nilgiris under the supervision of the Director, Nutrition Laboratories, Coonoor, dried and made into tablets of suitable size. The committee is now contemplating the production of a more concentrated form of vitamin C.

Substitutes for corks are being considered. These have become expensive and difficult to obtain owing to the war. Samples of wooden corks made by the Forest Research Institute, Dehra Dun, having two circular slots to increase resilience are being examined and are to be tried out on a large scale. Bottles with threaded glass necks and metal caps as well as bottles with crown corks are also considered as possible substitutes for bottles with corks.

BOMBAY MEDICAL COUNCIL

EXTRACTS from the proceedings of the Meeting of the Bombay Medical Council held on the 16th September, 1940.

At the outset, the registrar intimated that General Buckley, the president of the Council, regretted his inability to attend the Council meeting. In his unavoidable absence, therefore, Colonel Bhatia was voted to the Chair unanimously.

Government Notifications regarding the nomination of Dr. George Coelho, M.R.C.P., and the election of Dr. S. B. Gadgil, F.R.C.S., as members of the Council were read by the registrar. The chairman, Colonel Bhatia, then introduced Dr. Coelho and Dr. Gadgil to the meeting.

The Council passed a resolution by a majority expressing the opinion that in the absence of a common Indian language, medical education of the western type should be imparted through English as is done at present, for the time being. An amendment to the original resolution seeking postponement of the consideration of the question for the next meeting of the Council was declared lost.

It was decided to restore to the Bombay Medical Register the name of Dr. D. S. Pathre, M.B., B.S., removed under section 9 of the Bombay Medical Act, 1912, on 8th November, 1937, accepting the recommendation of the Executive Committee on that behalf.

In view of the impending retirement of General Buckley, the president of the Council, Colonel Bhatia, the Chairman, paid a glowing tribute to the career and services of General Buckley and a resolution moved from the Chair placing on record the appreciation of the Council of the valuable services rendered by General Buckley as President of this Council to the medical profession in general and to this Council in particular for nearly four years was passed unanimously.

The Treatment of Habitual Constipation

By F. S. LANGMEAD, M.B., F.R.C.P.

(From the *Medical Press and Circular*, Vol. CCIII, 17th January, 1940, p. 45)

CONSTIPATION is a relative term, for whilst some whose bowels are opened only two or three times a week are little, if at all, the worse for their infrequency, others if they miss one day suffer from headache, depression, sleeplessness, irritability and other disturbing symptoms. It is usual, however, to regard a patient as constipated in whom the food takes longer than about 48 hours to travel the length of the alimentary tract—a period which may be measured by the administration of charcoal.

In this short article no attempt will be made to consider the treatment of constipation due to some recognized organic disease of the alimentary tract or some general disorder such as myxoedema, but it will be limited to 'habitual' constipation—an apt term, for in its causation and treatment habit plays an important, indeed dominant, part. Such habitual constipation may begin in early infancy and persist, if untreated or treated late, throughout life. The prevalence of constipation is probably one of the prices which the community has to pay for its artificial order of life, for it is difficult to believe that under quite natural conditions constipation would be the bugbear that it is to-day. A community living mostly in the open, hunting for its food, eating largely of vegetables, and unhampered by the observances of modern social behaviour, would be unlikely to be troubled by constipation. Since a return to the state of primitive man is impracticable, our problem is to determine how it may be avoided and combated under the artificial conditions which foster it.

It is customary to consider constipation under two headings, that due to sluggish passage through the colon or 'colonic stasis' and that due to delay in the rectum or 'dyschezia'. Of these the latter is by far the most important and common; indeed, the more closely the subject is studied the more subsidiary is the place which colonic stasis is found to occupy in the causation of habitual constipation. In the ordinary case faeces are allowed to accumulate in the rectum until the normal reflex response is weakened or lost. This engenders further accumulation of faeces. Such a vicious circle has often been in control for a long time, perhaps for years, before advice is sought; the habit of daily evacuation has been lost and replaced by irregular defaecation secured by various adventitious aids, so that our effort to assist the patient to regain the normal reflex—which should be our main aim in treatment—may need to be prolonged, can only be useful if assisted by the full co-operation of the patient and, it must be confessed, may fail.

Prevention.—Despite the difficulties incidental to modern life, much may be done to prevent constipation. The baby from the first weeks of life should be trained to defaecate regularly, by being held over a receptacle at definite times. A suitable time is after a meal, and the reflex may be further 'conditioned' by approximating it to some event incidental to infant hygiene, such as bathing or exercise. Later the child should be trained to accept defaecation as a regular duty after a breakfast, thus taking advantage of the gastrocolic reflex; and also at all possible times to defaecate whenever the rectal stimulus is felt. It is obvious if this advice is to be followed that schools should provide ample lavatory accommodation. Its paucity, assisted perhaps by a false sense of modesty, may replace habitual defaecation by habitual constipation. The habit of giving purgatives to infants should be eschewed equally with that of administering a weekly purge to older children, which, though less prevalent

than in Victorian days, is still far too common, especially among the hospital class. Castor oil, especially, should be taboo, for after the irritant effect on the intestine has subsided it is followed regularly by constipation. Abuse of purgatives in general has played a prominent part in causing much of the constipation that the doctor is called upon to treat.

Curative.—It is not feasible to lay down a routine method of treatment for habitual constipation. Circumstances alter cases—and their treatment. It is futile to tell a patient with a rectum packed with dry faeces to take more exercise or eat brown bread; and it is harmful to treat all cases, regardless of their degree, by administering drastic purges. In the following brief summary of treatment an endeavour will be made to consider various lines of treatment *sciatim*, beginning with those which alone may suffice for milder cases and which play a part in the treatment of all. The problem is not 'What shall I give this patient to make his bowels open?' but rather 'How shall I treat this patient so that he opens his bowels regularly?'

(a) **Habit.**—The aim of curative treatment should be to regain the normal rectal reflex, just as in preventive treatment it should be trained, if necessary, and retained when present. The patient should be exhorted to attempt defaecation regularly after breakfast and to be prepared to spend some time in the attempt. A hurried visit to the lavatory en route to catching a train or bus does not suffice. The w.c. should be warm, the seat comfortable, and at such a height that the thighs are somewhat flexed.

(b) **Exercise.**—The general tone of the patient should, if possible, be improved by exercise, preferably in the open air. A round of golf before breakfast or a ride, walk or run, according to age and circumstances, may be attended by great improvement, as may also the 'daily dozen' when other exercise is not procurable. Exercises directed towards increasing the tone of the abdominal muscles are, of course, particularly suitable.

(c) **Diet.**—Careful inquiry should be made concerning the patient's habits with regard to food and drink. Irregular and snatched meals should be avoided if possible. It may be found, especially in the case of women, that meals are ordinarily taken without fluid, or that tea is drunk, strong and often, by itself—both habits which favour the disorder. Fruits, especially prunes and figs, vegetables, coarse porridge, brown bread and other foods which provide what the Americans dub 'roughage' are well recognized as being beneficial in moderate cases, but do not alone suffice in those that are more severe. If taken inordinately they may accentuate the trouble in a case in which the bowel is already loaded with scybala. They are particularly indicated in cases of so-called 'greedy colon', where absorption is excessive and the rapacious colon leaves little residuum to stimulate reflex action. Honey, manna and golden syrup are useful by virtue of a slight laxative action. In the case of infants, maltose may replace lactose or cod-liver oil with maltine may help. An early morning glass of hot water or cup of weak tea may be attended by success.

(d) **Lubricants.**—When hygienic and dietetic management are ineffective alone, lubricants are preferable to purgatives and may suffice. Such are paraffin or petroleum emulsion, or in the case of infants, olive oil. The well-known disadvantage of paraffin that it may escape unaware by the anus when the patient assumes the erect position is less troublesome if petroleum emulsion be used. These substances have a large field of usefulness, for if taken in sufficient amount, they do at least ensure that the motion is soft and reduce the likelihood of straining at stool—a dangerous practice to many, notably to patients with myocardial insufficiency or high blood pressure.

(e) **Purgatives.**—These should be avoided whenever possible and, if employed, always with the hope that they may happily be abandoned when other measures have had time to cause improvement. To tabulate a list of purgatives and to extol the particular virtues of each is beyond the scope of this article. Some may

be pleasant and effective to some patients, whilst definitely toxic to others. I can only suggest a few general rules, which, in my view, should govern their use.

(i) Choose a purgative which acts upon the large bowel rather than upon the small. 'Take care of the large bowel and the small will take care of itself' is a sound axiom. Such purgatives are saline, senna, aloes, sulphur and cascara—all of proved value. For the constipated dyspeptic, rhubarb, whatever its action may be, is advantageous, as is testified by the countless takers of the ubiquitous rhubarb and soda mixture. Calomel in my view, is unsuitable for the treatment of habitual constipation, useful as it may be for purging in other cases, where elimination of indigestible or decomposing food is required. It hurries the contents of the small intestine into the large and in too many instances causes severe colic. The same may be said of castor oil—a very useful eliminative but undesirable for habitual constipation. Purgatives containing vitamins, intestinal glandular extracts or bile salts have become popular for they often produce a satisfactory result without colic or discomfort.

(ii) If purgatives be necessary they should be given regularly and not each time that the bowels have not been opened for several days.

(iii) They should be given in doses large enough and often enough to ensure daily evacuation. When this has been attained it will often be possible, other forms of treatment being used, gradually to reduce first the dose and secondly the frequency until they can be abandoned.

(iv) *Enemata*.—In some cases constipation has reached the pitch where the rectum and colon are loaded with hard and dry faeces and where no treatment is likely to be effective until the bowel has been cleared of this burden from below by the use of enemata. Lavage with hot water or a simple enema

may be enough or recourse may be had to glycerine or warm olive oil. The effect of an enema may be enhanced by the use of a suppository, such as anusol, introduced at night, so that it may gradually permeate and soften the faeces during sleep. It may render the enema unnecessary.

Enemata should be regarded only as temporary measures to be abandoned as soon as possible, otherwise the patient may embark upon what proves to be an enema life. Especially advocated in children, but sometimes equally useful in adults is the soap cone, which may prove as active in evoking a colon response as an enema.

(v) *Massage*.—Though this is mentioned last it is by no means least. In a really intractable case when other methods have been tried over long periods, I have found that the addition of abdominal massage often meets with success. The effect, of course, is not immediate, in such cases, it should be persisted in.

I will conclude by mentioning a variety of constipation in infants which often goes unrecognized and is intractable to all ordinary forms of treatment—namely, anal spasm. In spite of active treatment the bowel fails to act regularly. If lubricants have been given, the infrequent motions may be found to be soft and would appear to give no cause for difficulty. The abdomen may become distended with flatus, the child suffering from colic and obviously in great discomfort. I have known abdominal operation for obstruction seriously considered in such a case. The diagnosis is made by rectal examination when the finger meets with a tense but yielding sphincter, the forcing of which leads to the passage of faeces and flatus and to prompt relief. The method of diagnosis embraces the treatment, for thereafter if the motions be kept soft, there is usually no further trouble. Other cases may require more prolonged or repeated stretching of the sphincter.

Reviews

CLINICAL PRACTICE IN INFECTIOUS DISEASES: FOR STUDENTS, PRACTITIONERS, AND MEDICAL OFFICERS.—By E. H. R. Harries, M.D. (Lond.), M.R.C.P., D.P.H., and M. Mitman, M.D. (Lond.), M.R.C.P., D.P.H., D.M.R.E. 1940. E. and S. Livingstone, Edinburgh. Pp. xii plus 468. Illustated. Price, 17s. 6d.; postage, 7d.

INFECTIOUS diseases play a very important part in the daily round of the general practitioner in temperate climates and to a less extent in the tropics. Nevertheless the attitude of the medical student is rather that 'fevers' is a dull subject that has to be 'got over' somehow. This was certainly the reviewer's opinion and this attitude was engendered by the fact that the process of 'doing fevers' entailed a dreary journey to a suburb where he was shown rashes which, like one's friends' wireless reception or gardens, were always 'so much better yesterday'. He also had very dull books in which to read up the subject for his examination. This new book appears to have some life in it. The introductory chapters are good and are designed to stimulate an intelligent interest in the subject; they are on such subjects as infection and resistance, hypersensitivity, allergy, anaphylaxis, serum reactions, transmission of infectious diseases, diagnosis, diet in infectious disease, etc.

The chapters on the common exanthemata of temperate climates, which are also common in hill stations in India, only occupy about a third of the book, and a good deal of space is given to diseases such as cerebro-spinal meningitis, dysentery, typhoid, undulant fever which are even more common in tropical than in temperate countries. The teaching is sound and up-to-date.

The illustrations are practical and the authors have faced the fact that most coloured plates of skin diseases are merely misleading.

We have a minor criticism: References have a minor place in a book of this kind but why be self-conscious about their absence or scarcity, and trot out the threadbare excuse that their inclusion only confuses the student, or words to that effect? Why assume that only students will read your book? Well-chosen references add very much to the value of a book; it is unnecessary to overload a book or paper with references in the worst American style—a bad practice which is creeping into medical publications in India. A reasonable excuse is that it takes a long time to check every statement associated with a reference and, as British writers don't usually relegate this work to secretaries, it would hold the book up for possibly some months. A second criticism is that sleeping sickness is not transmitted by the tick; this surprising statement appears in a table and is probably a misprint.

Otherwise the book is an excellent one which we can strongly recommend to students, practitioners, and teachers in this country.

MODERN DIETARY TREATMENT.—By Margery Abrahams, M.A. (Oxon.), M.Sc. (Columbia University), and E. M. Widdowson, B.Sc., Ph.D. (Lond.). Second Edition. 1940. Baillière, Tindall and Cox, London. Pp. xii plus 401. Price, 10s. 6d.

We reviewed the first edition of this book only three years ago and commented very favourably on it.

Our opinion seems to have been shared by others, for a second edition has been demanded within a very short time. The present edition is slightly enlarged

and has been revised throughout, as more information on the composition of food substances is now available. A few recent advances in medical treatment are reflected in the addition of diets suitable for patients on protamine zinc insulin, of low potassium diets for Addison's disease, and of low phosphorus diets for hypoparathyroidism; a recent retreat has been signalized by the exclusion of the now-obsolete ketogenic diet.

The book is an extremely practical one with a strictly scientific basis. We still think that the title is misleading and that 'Dietary in Modern Treatment' or some other variation not used already, would be better than the present one; it is not a book on treatment *by* dietary as the name implies. Its very practical nature is typified by the short section on Jewish dietary, and the consoling statement that it is against the tenets of the Jewish religion to fast on the day of atonement *against* the doctors advice.

It is a book that will be very useful in India, despite the fact that it is not written primarily for Indian patients.

APPLIED PHARMACOLOGY.—By A. J. Clark, M.C., M.D., F.R.C.P., F.R.S. Seventh Edition. 1940. J. and A. Churchill Limited, London. Pp. x plus 672, with 92 illustrations. Price, 21s.

It is three years since the sixth edition of this 'contemporary classic' was issued and many things have happened in the pharmacological field during these three years. The author apologises in the preface for the inadequacy of the treatment of the new subjects; the chapter on the sulphonamide group is admittedly short, but it provides an excellent outline, and, as the scene is changing so rapidly, detail would run the danger of becoming out of date before it was printed.

The chapter on endocrinines and vitamins have again been completely revised although they were only written for the last edition. A new and useful chapter on the pharmacology of the haemopoietic system has been included in this edition. In this chapter the author gives a classification of the anaemias, on modern lines, but most emphasis is laid on the treatment of the two main types by iron and liver extract, respectively. The chapter provides a good account of the subject, though the statement that 'a total daily dose of 3 gr. of ferrous sulphate in this form [tablet] is effective in microcytic anaemia' is misleading, as there is no indication that he is discussing minimum dosage; a dose of 3 to 6 times this amount is usually given. One is a little disappointed that there is not more about iron metabolism, for a great deal of work has been done on this subject, and, though we have still much to learn, a few definite facts regarding iron absorption, retention, utilization, and excretion have been established.

The present requirements are not lost sight of and important information will be found in the chapter on disinfection of wounds. With reference to sulphonamides the author says that 'these reduce the ceiling of air pilots', a very useful thing to be remembered, but why not 'lower the ceiling' and maintain this very descriptive metaphor?

To produce this book at all under present conditions is very creditable and we do not see much evidence of either the 'hurry' or 'the special difficulties' to which the author refers in his preface. The present edition will certainly enhance the established reputation of this book.

ELECTROCARDIOGRAPHIC PATTERNS: THEIR DIAGNOSTIC AND CLINICAL SIGNIFICANCE.—By A. R. Barnes, M.D. 1940. Charles C. Thomas, Springfield, Illinois. Pp. 193, with 94 illustrations. Obtainable from Ballière, Tindall and Cox, London. Price, 27s. 6d.

In the recent years, study of the various electrocardiographic patterns associated with myocardial disease and the introduction of chest leads has opened up new possibilities of accurate estimation of cardiac disorders. This book, written by one whose contribution to recent knowledge of the subject is considerable,

describes the electrocardiographic patterns in different varieties of heart disease.

The book consists of nine chapters. A chapter has been allotted to the discussion of the relation of the distribution of the coronary arteries to acute myocardial infarction. The other chapters deal with the electrocardiographic patterns in myocardial infarction, in predominant ventricular strain, in acute and chronic right ventricular strain, and in pericarditis, the effect of certain drugs, metabolic disorders and infections on the electrocardiogram. The last chapter is devoted to a detailed consideration of the subject of precordial leads. Each chapter is well illustrated with numerous tracings and the mode of presentation of the subject is admirable. There are numerous short case notes with series of electrocardiograms to illustrate the various patterns encountered in different types of cardiac disease.

The printing, get-up and illustrations are excellent. The book will prove to be of great interest to the cardiologists.

P. C. S. G.

BLOOD GROUPS AND BLOOD TRANSFUSION.—By Alexander S. Wiener, A.B., M.D. Second Edition. 1939. Ballière, Tindall and Cox, London. Pp. xvii plus 306, with 52 illustrations. Price, 27s. 6d.

The first edition of this book, in 1935, became the standard work on the subject, in English. The present edition, in which additional matter covering 86 pages has been embodied, is welcome and will certainly maintain the reputation of the first edition.

With a view to increasing further the utility of this useful book three major suggestions are offered for the next edition: (i) Mathematics may be reduced. (ii) More macroscopic methods of haemagglutination may be described. (iii) In introducing genetics the traditional cryptic symbolism which uses T for the DOMINANT character TALL and t for the recessive character dwarf may be modified. T for TALL and d for dwarf are the most obvious symbols. The letter t for dwarf is unnecessarily cryptic and an embarrassment in the consciousness in following the products of the allelomorphs.

Then there are three minor points: (i) The 'indirect evidence as to the duration of life of the red blood corpuscles', on page 55, is really direct evidence. (ii) The age of the transfused corpuscle of the same group, but not of the same type, is now known to be 100 days instead of 'seven weeks'. (iii) In table 5, O should be above A.

The paper, printing and binding are good. No printer's errors arrest attention. The price perhaps could be lower.

S. D. S. G.

INTRODUCTION TO CARBOHYDRATE BIO-CHEMISTRY.—By D. J. Bell, B.Sc. (Glas.), M.A. (Camb.), Ph.D. (St. Andrews), A.I.C. 1940. University Tutorial Press Limited, London (Clifton House, Euston Road, N.W.1). Pp. viii plus 112. Price, 3s. 6d. Obtainable from Oxford University Press, Bombay and Calcutta

This handy little volume is intended particularly for students of biochemistry and the aspects of knowledge which a student has to seek from diverse sources are correlated in this volume. It begins with a brief account of photo-synthesis which is followed by the recent views about the structure of monosaccharides, disaccharides and polysaccharides. It then discusses the biochemical events which result in the liberation of energy in living cells, as in alcoholic fermentation, or in animal tissues, as in muscle glycolysis. The recent discoveries on the hydrolysis and synthesis of sugars and polysaccharides by means of enzymes, the nature of uronic acids, plant glycosides, nucleotides and related substances, the polysaccharides of bacteria, moulds and yeasts and the decomposition of carbohydrates by bacteria, are all briefly discussed in turn. For the benefit of the more advanced students and for the assistance of pure chemists and biologists the author has included the references to the more interesting and

fundamental original papers and to general reading. Written by one who had several years of close touch with modern research in the field, the book should be welcome, not only by biochemists but also by other men of science who desire to possess an up-to-date knowledge of this subject without hunting the larger and more costly textbooks on biochemistry which soon become out of date.

S. G.

ADVICE TO THE EXPECTANT MOTHER ON THE CARE OF HER HEALTH AND THAT OF HER CHILD.—By F. J. Browne, M.D., D.Sc., F.R.C.S.E., F.R.C.O.G. Fifth Edition. 1940. E. and S. Livingstone, Edinburgh. Pp. 48. Price, 6d.; postage, 2d.

It is a clear sign of the times that the first chapter of this admirable little book is devoted to the importance of antenatal care and the chief abnormalities against which it is designed to protect the expectant mother. The text of 46 pages is throughout simple, clear and never wordy. The chapters on the common disorders of pregnancy and on diet deserve special mention.

Although the book is intended for the expectant mother it contains much to recommend it to the nurse, midwife and health visitor, and indeed the young general practitioner may find in it solutions of his early problems, presented in a simple and compact form.

Abstracts from Reports

ANNUAL REPORT OF THE HEALTH DEPARTMENT OF THE MUNICIPALITY OF SINGAPORE FOR THE YEAR 1939

APART from one case of smallpox, we enjoyed another year of complete freedom from the dangerous infectious diseases, smallpox, cholera and plague.

The case of smallpox was in a young Chinese girl who had lived at 50, New Market Road for at least five months prior to the date of onset of the disease. Though exhaustive enquiries were made the source of the infection could not be traced, and no connection with any previous case could be established.

Except for the decrease in the incidence of typhoid, and the increase in the number of diphtheria cases notified, nothing calls for special comment.

It might, however, be well to point out that the increased incidence of the typhus-like diseases is probably due to improved diagnosis rather than to a true increased incidence in these diseases. Weil-Felix reactions are now carried out in all suspicious cases, and some positive reactions have been obtained which have enabled a diagnosis to be made which otherwise would probably have been missed.

Under the heading of typhus in the returns are included rural-type tropical typhus, Japanese river fever and urban-type tropical typhus. Epidemiological evidence has been obtained that *T. akamushi* and *T. deliciensis* are the vectors of rural-type tropical typhus and Japanese river fever which are now considered to be the one disease. There is laboratory evidence that the virus of the urban type can be transmitted by the rat flea. Louse-borne typhus has not been seen in Singapore or Malaya.

With regard to leprosy, it is possible that the increased number of cases notified is due to earlier and improved diagnosis, and to patients coming forward more readily for advice and treatment. With the relaxation of the conditions, under which cases may now be treated in their homes, under the new leper rules which came into force during the year, there is probably less inducement to conceal cases of this disease.

The usual routine rat-trapping laid down by the International Sanitary Convention was carried on throughout the year. Three thousand two hundred and eighty-three rats, trapped in the town and port areas, were examined in the laboratory. None was plague-infected. The flea index remained low, being only 1.08 per live rat against 1.06 in the previous year.

It may be of interest to record that four deaths from leptospirosis (Weil's disease) and two from encephalitis lethargica were certified during the year.

ROLE OF CALCIUM GLUCONATE AND IODINE IN WHOOPING COUGH

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—In an Indian family, four children were suffering from whooping cough. Two were girls 9 and 3 years old and two were boys 5 and 2 years old. On account of getting fits of whooping cough at very short intervals, the conjunctivæ of their eyes were congested and none of them could retain food or sometimes even water. The result of this malady was that they were getting thinner and weaker. All different medicines by mouth were tried but they could not get any relief. As a last resort it was thought to give injection of 2 c.cm. 10 per cent solution calcium gluconate c. iodine. Each child was given 2 c.cm. intramuscularly. After twenty-four hours it was observed that each of them could retain one meal during 24 hours. This slight improvement led me to try a further injection of 2 c.cm. each on the third day. To my great satisfaction I found that the fits of whooping cough were greatly reduced in number and the power of retention was markedly improved. Four more injections were given after an interval of four days. In all, six injections were given to each of them.

The result of the six injections was that they made an uneventful recovery and at the end of the treatment they were looking brighter, happier, and greatly improved in health.

Service Notes

APPOINTMENTS AND TRANSFERS

On recall to military duty Lieutenant-Colonel G. A. Khan, Superintendent, Borstal Institution, Lahore, made over charge of his duties to a non-I.M.S. officer on the afternoon of the 14th October, 1940.

Lieutenant-Colonel M. P. Atkinson, an Agency Surgeon, is employed as Chief Medical Officer, Western India States Agency, and Residency Surgeon, Rajkot, with effect from the forenoon of the 23rd October, 1940.

Major G. W. Miller is appointed to officiate as Deputy Public Health Commissioner with the Government of India during Major C. K. Lakshmanan's absence on leave.

On recall to military duty Captain C. F. Garfit, Civil Surgeon, Murree, made over charge of civil medical duties on the 2nd November, 1940.

Captain H. B. Wright is attached as an additional officer to the Medical Store Dépôt, Lahore Cantonment, with effect from the forenoon of the 4th November, 1940, until further orders.

On recall to military duty Captain H. H. Mahmud, Superintendent, Central Jail, Lahore, made over charge

of his duties to a non-I.M.S. officer on the afternoon of the 19th November, 1940.

The following appointments are made:—

INDIAN LAND FORCES

(Emergency Commission)

To be Captain (on probation)

Shreedhar Damodar Dalal. Dated 23rd September, 1940, with seniority from 23rd September, 1936.

To be Lieutenants (on probation)

23rd September, 1940

Nripendra Mohan Khan Bhaduri.

Muhammad Sunawar Ali Laskor.

Iswar Chandra Misra.

Harishehanda Paul.

Nawabzada Ali Ahmad Khan.

Atma Singh Baxi.

Krishnaswami Ayyar Subramania Ayyar.

James John Dharmraj.

Panachayil Pinumootil Varkey George.

Navanithakrishnan Money.

Manohar Lal Gaind.

Nemam Echambady Sarangapani.

Hakim Nazir Hussain.

Abdullah Khan Marwat.

Phanindra Nath Banerjee.

Mitranand Sharma.

Shah Mohammad Quamrul Hoda.

Indar Sen Jetley.

Kallankandeth Narayan Kutti Menon.

Krishnalal Atri.

Samuel Victor Joseph.

Homi Naoroji Dastur.

Ponnambalam Pillai Kailasam.

Pulikottil Ittoop Jacob.

Karipaparambil Dominic Sebastian.

Cheriyan Pallath Cheriyan.

Mukund Balkrishna Kekre.

Arathil Candeth Sreedharan Nambiar.

Palathinkal Ithack George.

Satyendra Nath Basu.

Bhamidipati Joga Rao.

Sailesh Chandra Ray.

Sailendra Kumar Ghosh.

Kalika Charan Dube.

Rameshendra Manjanath Nadkarni.

Bhaskar Shantaram Wagley.

Simili Ponnuswami Ramakrishnan.

Kailash Narayan Mathur.

Padmanabha Ananta Narayan.

Budh Singh Sharma.

Vasant Ramehra Bagwe.

Madhav Raghunath Thakar.

Abdul Aziz.

Jagannath Haribhai Patel.

Shyam Bahadur Sinha.

Stanislaus Mascarenhas.

Debi Das Mitra.

Partul Chand.

Mohammad Saghir Yehya.

Mohammad Said.

PROMOTIONS

Colonel to be Major-General

R. H. Candy, C.I.E. Dated 31st October, 1940.

Captains to be Majors

A. H. O'Malley. Dated 25th September, 1940.

M. Singh. Dated 15th November, 1940.

RETIREMENTS

Colonel D. F. G. Murphy, M.C., V.M.S. Dated 8th November, 1940.

Lieutenant-Colonel C. H. P. Allen. Dated 5th December, 1940.

The following retirements, with gratuity, is permitted:—

INDIAN LAND FORCES

(Short Service Commission)

Captain S. Sunkavally. Dated 2nd October, 1940.

Captain K. S. Aiyer. Dated 22nd October, 1940.

Notes

THE EMERGENCY CADRE OF THE INDIAN MEDICAL DEPARTMENT

WANTED medical licentiates or graduates for appointment as sub-assistant surgeons in the emergency cadre of the Indian Medical Department.

Rank—Jemadar.

Pay — Jemadars 75-5-145.

Pay — Subadars 160-5-175.

Allowances—Civil (Rs. 50/- p.m. to all), hair cutting, washing free.

Accommodation and rations—Free or compensation in lieu.

Travelling concessions—One and a half second class from ordinary place of residence to place of interview and back, with daily allowance for halt. Railway warrant on appointment.

Full particulars of terms and conditions and application forms obtainable from the undersigned.

P. S. MILLS,

MAJOR-GENERAL, I.M.S.,

Surgeon-General with the Govt. of Bengal.

COATES AND COOPER (GYNOMIN)

New Offices.—Messrs. Coates and Cooper, Limited, have established offices at 21, Eastbury Road, Northwood, Middlesex, England, to which address all communications should be directed.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints gratis; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

The preparation of reprints entails rearranging the type, so that there is often a delay of a month or more, after the publication of the *Gazette*, before the reprints are ready. If reprints are not received within two months of publication of the *Gazette*, contributors should write to the Publishers.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

CLINICAL OBSERVATIONS ON LANDRY'S PARALYSIS

(BASED ON A STUDY OF 10 CASES)

By J. C. BANERJEA, M.B., M.R.C.S. (Eng.),
M.R.C.P. (Lond.)

Hony. Jr. Visiting Physician, Medical College Hospital
and

M. N. DE, M.B., M.R.C.P. (Lond.)
Professor of Medicine, Medical College, Calcutta

LANDRY, in 1859, described a disease characterized by an acute flaccid paralysis beginning in the lower limbs and rapidly spreading upwards to involve the trunk, upper limbs, neck, the bulbar and the respiratory centres. Since then, this syndrome of acute ascending paralysis has been observed by various workers in a number of diseases associated with gross pathological lesions of the nervous system, such as (a) an ascending form of acute anterior poliomyelitis, (b) acute ascending myelitis, (c) acute polyneuritis, specially of diphtheritic origin, (d) intrathecal haemorrhage, (e) post-vaccinal and post-erythematous (smallpox and measles) encephalomyelitis, (f) rabies, and rarely (g) disseminated sclerosis (Brain, 1933). This syndrome has also occasionally occurred in the course of typhoid fever and antirabic inoculation. It is therefore desirable, in the interest of clarity, that the use of the term 'Landry's paralysis' should be confined to those cases of acute ascending paralysis where sensory and sphincteric disturbances are little or absent, muscular wasting is never marked, recovery is complete among the survivors and gross pathological changes in the nervous system are absent in the autopsy cases.

Aetiology

The aetiology of the disease is not definitely known. It is probably an acute form of polyneuritis of toxic or infective origin. The close resemblance of the disease to some cases of acute anterior poliomyelitis, post-vaccinal encephalomyelitis and rabies is strongly suggestive of an infection by a neurotropic virus. The infective agent has probably a selective affinity for the lower motor neurones, irrespective of the mode of entry, whether *via* the bloodstream or the axis cylinders of the olfactory nerves. The possibility of a bacterial infection is extremely doubtful, though Buzzard (1903) attributed some of his cases to a bacterial agent, a micrococcus.

Pathology

On a naked-eye examination the spinal cord and specially its grey matter show some hyperaemia with a few punctiform haemorrhages.

Microscopical examination reveals vascular engorgement and varying grades of degenerative changes in the anterior horn cells and the cells of Clarke's column, such as chromatolysis and diffuse fatty changes. These changes are most marked in the lumbo-sacral enlargement which is the seat of the first paralysis. Perivascular infiltration, neuronophagia and neuroglial proliferation are absent. Slight fatty changes may be seen in the skeletal muscles. The cerebro-spinal fluid is clear and may show normal or increased pressure. The protein content is normal or slightly increased. The cell content is either normal or may show a slight lymphocytosis. In one of our cases the lymphocyte count was 20 per c.mm. Spontaneous coagulation of the fluid due to a high protein content has been reported by some observers. Enlargement of the liver, spleen and mesenteric lymph nodes is not infrequent.

Clinical features

Incidence.—Landry's paralysis is undoubtedly a rare disease. There were only seven cases in 49,284 admissions into the Medical College Hospital during the last 14 years, viz., 1926 to 1939. We came across three cases in the Howrah General Hospital during the last 5 years 1935 to 1939. According to Aring (1936) there were only seven cases in about 30,000 admissions into the Boston City Hospital from 1st September, 1933 to 1st August, 1934. The disease occurs usually between 16 and 54 years (Collier and Adie, 1929). In our series the age incidence was between 15 and 37 years. Males are more frequently affected than females. The ratio of males to females is 9 : 1 in our series.

Mode of onset.—The onset, though sometimes sudden, is usually gradual, ushered in by certain prodromal symptoms such as malaise, headache, insomnia, slight fever, anorexia, vomiting, diarrhoea, dull aching pains in the back and limbs and numbness of the extremities. In our series, the premonitory symptoms were as follows:—slight or moderate fever in six cases, vomiting and diarrhoea in one, pain and tingling sensation in the limbs in two and transient stiffness of the neck in one. It is interesting to note that in two cases premonitory symptoms were conspicuously absent.

Psychical functions.—Consciousness is retained throughout the illness. Intelligence, memory and judgment are unimpaired. Speech is usually normal.

Cranial nerve functions.—The cranial nerves are usually not involved except in severe cases. We have noted the infra-nuclear type of facial paralysis in three cases (unilateral in two, bilateral in one), dysphagia in four, hoarseness of voice in two, palatal paralysis in three, and diminished sensibility over the area of supply of the trigeminal nerve in one. Nystagmus indicating an involvement of the vestibular nerve or the cells of Clarke's column was

observed in one case. The occurrence of diplopia or ptosis has been reported in the literature, but we have not come across any such symptoms.

Motor functions.—Weakness first appears in the muscles of the lower limbs, one limb being affected a few hours earlier than the other. The proximal muscles are more affected than the distal, so that the movements of the fingers and toes may be present, though the limbs cannot be moved. In severe cases, the paralysis rapidly spreads upwards, in the course of a few hours to a few days, involving successively in the order of their innervation from the spinal cord, the muscles of the trunks, upper limbs, neck and those supplied by the bulbar nuclei. In some cases the muscular weakness may start in the face, neck or the upper limbs and then spread downwards to the trunk and the lower limbs. Such a descending type of Landry's paralysis was observed in two of our cases (*vide* cases 1 and 10). The paralysed muscles are flaccid and slightly tender on pressure. Wasting is usually absent but it may occur in a moderate degree, in cases where recovery is delayed beyond 2 or 3 weeks. It was present in two of our cases. Fibrillary tremors are absent. The electrical reactions are usually normal, but in cases associated with muscular wasting a partial reaction of degeneration may be present, as in two of our cases.

Sensory functions.—In most cases there is no objective loss of sensation. In three out of ten cases, a blunting of the sensibility to light touch and pin-prick over the distal parts of the limbs was present. In one of these three cases there was, in addition, a diminished sensibility of the conjunctiva and cornea with astereognosis and loss of sense of position in the fingers and toes.

Reflexes.—The superficial and deep reflexes are either absent or diminished in the affected area. The plantar reflex, if present, is flexor. In our series the deep reflexes (knee and ankle jerks) were absent in all, the superficial reflexes were absent in seven, sluggish in one and present in two. The functions of the sphincters are, as a rule, unimpaired though occasionally, as in two of our cases, retention of urine may occur in the early days but it clears up spontaneously in a few days. Some difficulty in emptying the rectum may also be present as in one of our cases.

Trophic functions.—Vasomotor changes or changes in the nutrition of the skin and nails are absent. Bed-sores are not known to occur.

Constitutional symptoms.—The constitutional symptoms are usually mild. The disease is, in most instances, afebrile except in the presence of bronchial or pulmonary complications. In six out of our ten cases the course was febrile.

Blood picture.—There is no distinctive blood picture of the disease. The average total

leucocyte count was 7,063 per c.mm., the maximum being 11,856 and the minimum 6,500.

Course and prognosis.—In unfavourable cases which constituted about 60 per cent of the total number in our series, the paralysis extended in the course of 6 to 13 days, either to the cervical region of the spinal cord, causing death by respiratory failure, or to the muscles of deglutition leading to death from aspiration bronchopneumonia. Out of six deaths in our series, five were due to respiratory failure and one was due to bulbar paralysis. In two of the fatal cases respiratory failure was associated with diaphragmatic paralysis. In favourable cases, the paralysis ceases to spread and convalescence begins. The power of movement gradually returns, first in those muscles which were affected last. The distal muscles of the limb recover earlier than the proximal. A period varying from 3 to 6 months is often required for complete recovery. In two of our cases the recovery period was 2 and 4 months, respectively. In two other cases recovery was not complete even after 7 months and 2 years of convalescence. The occurrences of relapses and recurrences are unknown.

Diagnosis

The diagnosis of a typical case of Landry's paralysis presents little or no difficulty. The onset of a rapidly spreading flaccid paralysis of the limbs and trunk, the absence of muscular wasting, sensory loss and sphincter disturbances and the occurrence of complete recovery if the patient survives are diagnostic features of the disease. Of course, in atypical cases the presence of slight sensory loss, muscular wasting with reaction of degeneration and sphincteric disturbances may throw doubt as to the real nature of the disease, but it must be remembered that these clinical features *per se* do not contra-indicate the diagnosis of Landry's paralysis. In such cases, however, before arriving at a diagnosis we have to differentiate it from (a) acute ascending type of poliomyelitis, (b) acute ascending myelitis and (c) intrathecal haemorrhage.

From the acute ascending type of poliomyelitis, it is distinguished by (i) its rarity in childhood, (ii) wide-spread nature of the paralysis, and (iii) absence of high fever, signs of meningeal irritation, marked muscular wasting and reaction of degeneration. A high polymorphonuclear leucocytosis in the peripheral blood with a lymphocytosis in the cerebro-spinal fluid is strongly suggestive of poliomyelitis. The presence of a residual wasting on recovery excludes the diagnosis of Landry's paralysis.

From acute ascending myelitis it is easily differentiated by the absence of severe sensory loss below the level of the lesion, sphincteric disturbances, bed-sores, and Babinski's sign (unless the lumbo-sacral enlargement of the cord is affected or the transverse lesion is severe and complete). Moreover, in the former disease,

the motor paralysis, sensory loss and the sphincter paralysis occur simultaneously. Besides, acute myelitis is often of syphilitic origin and hence associated with a lymphocytosis of the cerebro-spinal fluid and a positive Wassermann reaction of the serum and cerebro-spinal fluid. Intrathecal haemorrhage is distinguished from Landry's paralysis by the simultaneous appearance of motor paralysis, sensory loss and sphincter incontinence, and by the presence of hemorrhagic cerebro-spinal fluid.

The distinction of Landry's paralysis from acute polyneuritis is artificial and of no practical value. Both the conditions have analogies on pathological and clinical grounds. Both are due to a toxic blood state and the toxic agent in both has a selective action on the lower neurones, both motor and sensory. In fact, in some instances of acute polyneuritis due to rabies, lead poisoning, diphtheria, and experimental curare poisoning, the selective action of the toxin is confined to the lower motor neurones only.

Treatment

In the absence of any specific remedy the treatment consists in (a) the maintenance of general body resistance by adequate nutrition and correction of associated anaemia, if there be any, (b) the elimination of the hypothetical toxins by diuretics, enemata, mild purgatives and daily drainage of cerebro-spinal fluid, (c) prevention of complications, and (d) relief of symptoms.

(a) Maintenance of the body resistance : For this purpose adequate nourishment is essential. The diet should be light and easily assimilable and yet should consist of the necessary quantities of proteins, fats, carbohydrates and vitamins, specially vitamin B₁. If there is an associated anaemia, it must be treated with the appropriate drugs, *viz.*, iron in large doses or liver-extract injections, according as it is hypochromic or hyperchromic.

(b) Elimination of toxins : Toxins are usually eliminated by the skin, kidneys and the bowels. Hence the administration of a diuretic and diaphoretic mixture and of mercurial purgatives is useful in ensuring elimination. Some of the toxin is circulating in the cerebro-spinal fluid and daily withdrawal of 15 to 20 c.cm. of cerebro-spinal fluid by a lumbar puncture will certainly reduce the toxic load and help the recovery of the nerve cells.

(c) Prevention of complications : The most serious complication that is to be guarded against is the paralysis of the respiratory and bulbar muscles. The patient should be propped up to help respiration and prevent hypostatic congestion. Hypodermic injections of strychnine sulphate in doses of grain 1/16, twice a day, to adults have been very helpful. Collier and Adie (1929) advocate injection of atropine to check the progress of the respiratory paralysis

and to prevent the accumulation of exudates in the bronchioles which may lead to collapse broncho-pneumonia. We have had beneficial results in some of our cases from the daily administration of vitamin B₁ (thiamine chloride), in the form of betaxin, in doses of 4,000 international units for 2 weeks. When respiratory paralysis supervenes artificial respiration should be continued with the aid of a Drinker's apparatus till the crisis is over. In cases of bulbar paralysis, there is great difficulty in feeding and maintaining nutrition. Besides, aspiration broncho-pneumonia is a common complication. In such cases feeding by the nasal or oesophageal tube should be resorted to. The mouth should be kept scrupulously clean by the use of antiseptic washes.

(d) Relief of symptoms : The symptoms such as pain, pyrexia and retention of urine are fortunately not persistent. Still the use of analgesics and antipyretics, such as aspirin and salicylates, is indicated in the presence of pain and pyrexia. If there is retention of urine the bladder should be catheterized every 8 hours under strict aseptic precautions.

Case reports

Case 1.—S., Muslim, male, aged 24 years, was admitted on 27th September, 1937, with the complaint of inability to move both the upper and lower limbs. This developed in the course of 3 days about 2 weeks before admission. The order of affection was right fingers, right forearm, right arm, left fingers, left forearm, left arm and then the legs. He had no premonitory symptoms, nor did any constitutional disturbance accompany the paralysis. Past history—kalaazar 14 years back. Family history—nothing contributory. Personal history—an employee in Bata Shoe Co., Ltd. He prepared rubber sheets for soles of shoes. Moderate smoker. No other addiction. None else in the workshop similarly affected. General examination—average build and nutrition. No anaemia, cyanosis, or jaundice. Temperature—98.4°F. Pulse/respiration—72/20. Nervous system—higher cerebral functions unimpaired; sleep—good; speech—normal. Cranial nerve functions—normal. Motor functions—loss of power in the muscles of both upper and lower limbs, more marked on the right side. Muscles—slabby, no wasting noticed on admission, but he developed some degree of wasting during the course of the illness. Fibrillary twitching absent. Sensory functions—unimpaired. Calf muscles slightly tender on pressure. Reflexes: abdominal reflex—sluggish; plantar reflex—flexor and sluggish; deep reflexes—absent; sphincters—normal. Trophic functions—normal. Alimentary system: spleen—just palpable; liver—not palpable. Respiratory system—no abnormality detected even though a careful watch was kept for any sign of involvement of the diaphragm and inter-costal muscles. Cardio-vascular and urinary systems showed no abnormality. Laboratory findings—Blood: haemoglobin—80 per cent; leucocytes—9,900 per c.mm.; polymorphonuclears—56 per cent. Wassermann reaction—negative. Electrical reaction—partial reaction of degeneration in the affected muscles. Patient was discharged on 1st February, 1938. Cured without any residual paralysis.

Case 2.—P. K. M., developed Landry's paralysis in the course of an attack of epidemic dropsy. He was admitted on 25th July, 1938, with the following complaints:—(i) Swelling of the feet and legs with a red flush for 10 days, (ii) fever varying between 101°F. and 100°F. for the first 5 days, none for the last 4 days, (iii) inability to move the lower limbs for 3 days, (iv) difficulty in swallowing for 3 days,

(v) nasal intonation of voice for 2 days, (vi) palpitation for 10 days and (vii) hoarseness of voice for 5 days. Past history—nothing of importance. History of epidemic dropsy in the family. Personal history nothing contributory. General examination—patient toxic, no anaemia; cyanosis or jaundice. Temperature— 100°F . Pulse/respiration—152/38. Nervous system—higher cerebral functions—normal; sleep—good; speech—normal. Cranial nerve functions—paresis of the soft palate and right side of the face; hoarseness of voice and dysphagia; no other abnormality. Motor functions—paralysis of the muscles of the lower limbs and paresis of the muscles of the upper limbs. Sensory functions unimpaired. Both superficial and deep reflexes absent. Sphincters normal. Trophic changes absent. Skull and vertebral column normal. Respiratory system—air entry into lungs moderate. Alimentary system—tongue thickly coated and dry; liver enlarged two fingers and tender; spleen—not palpable. Cardio-vascular system—heart sounds weak and rapid. Urinary system—nothing abnormal. Laboratory findings—Blood: haemoglobin—70 per cent; leucocytes—7,126 per c.mm.; polymorphonuclears—80 per cent. Sedimentation rate 37.5 mm. per hour. Patient succumbed on 28th July, 1938, on the 12th day of the illness, from paralysis of the diaphragm.

Case 3.—A. B. D., Hindu, male, aged 37 years, was admitted on 26th July, 1938, with the following complaints:—(i) Pain in the legs, (ii) inability to move the lower limbs and (iii) fever. He had at first pain in the medial aspect of the thighs but this extended down to the legs later on. Fever developed 2 days later and paralysis of the lower limbs 3 days later. Past, family and personal history—nothing of importance. General examination—build and nutrition—poor; anaemia present; no jaundice or cyanosis. Temperature— 100°F . Pulse/respiration—118/26. Nervous system—higher cerebral functions unimpaired; sleep—good; speech—normal. Cranial nerve functions normal. Motor functions—paralysis of the muscles of the lower limbs. Paresis of the muscles of the upper limbs. Sensory functions normal. Some wasting of the paralysed muscles present. Fibrillary twitchings—absent. Reflexes—superficial reflexes absent; knee and ankle jerks absent; biceps, triceps and supinator jerks normal. Sphincters—control of the vesical sphincter was lost but is now normal; defecation normal. Trophic functions normal. Skull and vertebral column normal. The respiratory, alimentary and circulatory systems showed no abnormality. Laboratory findings—Blood: haemoglobin—65 per cent; leucocytes—9,672 per c.mm.; polymorphonuclears—79 per cent. Urine—*B. coli* on culture. No abnormality detected in the stool. Patient was discharged on 3rd September, 1938, in a much improved condition.

Case 4.—L. P., Chinese, male, aged 25 years, was admitted with the following complaints:—(i) weakness of both upper and lower limbs, (ii) fever, (iii) difficulty in breathing, and (iv) difficulty in swallowing solid food. He developed the above complaints in the course of 10 days in the following order: fever, weakness of the lower limbs and weakness of the upper limbs. Past, family and personal history—nothing contributory. General examination—build and nutrition moderate. Cyanosis present; no jaundice or anaemia. Nervous system—higher cerebral functions unimpaired; speech normal; sleep good. Cranial nerve functions—difficulty in swallowing solid food; no other abnormality. Motor functions—loss of power in the muscles of both upper and lower limbs; slight wasting; fibrillary twitchings absent. Sensory functions unimpaired, only tender calf muscles during the early stage. Deep reflexes absent. Trophic functions unimpaired. Skull and vertebral column normal. Respiratory system—sucking in of the epigastrium during inspiration (paralysis of diaphragm); rate 30 per minute. Cardio-vascular and alimentary systems—nothing abnormal. Laboratory findings—Blood: leucocytes 6,500 per c.mm., polymorphonuclears 69 per cent. Wassermann reaction negative. Urine and stool—nothing abnormal. Patient died of respiratory failure on the 13th day of the illness.

Case 5.—N. K. B., Hindu, male, aged 20 years, was admitted with the following complaints:—(i) paresis of the upper and lower limbs for 5 days, weakness first developed in the lower limbs, (ii) intermittent fever, (iii) nasal intonation of voice for 5 days and (iv) difficulty in swallowing liquids. Past and family history—nothing contributory. General examination—build and nutrition average. Cyanosis present. Temperature— 100°F . Pulse/respiration—104/36. Nervous system—higher cerebral functions normal; sleep normal; speech normal. Cranial nerve functions—nasal voice (paralysis of the soft palate); difficulty in swallowing liquids; no other abnormality. Motor functions—paresis of the muscles of the upper limbs; complete paralysis of the muscles of the lower limbs; no wasting. Fibrillary twitchings absent. Sensory function unimpaired. Reflexes—both superficial and deep reflexes absent. Sphincters normal. Trophic changes—nil. Skull and vertebral column—normal. Respiratory system—sucking in of the epigastrium during inspiration (paralysis of diaphragm). Alimentary and cardio-vascular systems—nothing abnormal. Died of respiratory failure on the 8th day of the disease.

Case 6.—S. B., male, aged 30 years, admitted on 31st December, 1937, with all the signs and symptoms similar to those of N. K. B. (case 5) except that there was no paralysis of the diaphragm. The bulbar involvement was more marked. Patient died on 1st January, 1938, on the 6th day of his illness, 24 hours after admission.

Case 7.—K. S., Buddhist, aged 25 years, was admitted on 4th April, 1939, with the following complaints:—(i) fever—5 days, (ii) severe pain in left lower limb—3 days; the pain spread to the right lower limb the next day, (iii) loss of power of the left lower limb—3 days, (iv) loss of power of the right lower limb—2 days and (v) retention of urine—24 hours. The patient took some purgative 4 days back as a result of which he had six loose stools and two vomits and then he developed the above complaints. General examination—patient exhausted; build and nutrition—moderate. Nervous system—higher cerebral functions normal. Cranial nerve functions—nystagmus present; no other abnormality. Motor functions—paralysis of both lower limbs; no wasting. Fibrillary twitchings absent. Neck slightly rigid. Sensory functions—unimpaired. Reflexes—superficial: abdominal present; plantar—no response. Knee and ankle jerks absent; biceps and triceps jerks sluggish. Sphincters—retention of urine, no evacuation of the bowels; patient had to be catheterized and given enemas. Trophic changes—nil. Skull and vertebral column normal. Respiratory, alimentary, urinary and cardio-vascular systems revealed nothing abnormal. Laboratory findings—Blood: haemoglobin 70 per cent; leucocytes 11,856 per c.mm.; polymorphonuclears—74 per cent. Urine and stool—nothing abnormal. Blood urea—50 mg. per cent. Wassermann reaction—negative. Electrical reaction—reaction of degeneration in the muscles of both lower limbs. Patient was discharged on 21st May in a much improved condition; sphincters became normal; power in the lower limbs was gradually returning and the patient could move his right great toe.

Case 8.—Mrs. R., Anglo-Indian, female, aged 37 years, was admitted on 2nd June, 1935, with the following complaints:—(i) pain and tingling sensation all over the body, (ii) prickling sensation in the hands and feet and (iii) inability to walk or stand. General examination—build and nutrition moderate. Jaundice, anaemia and cyanosis—nil. Temperature— 98.4°F . Pulse/respiration—84/24. Nervous system—higher cerebral functions unimpaired; sleep normal; speech normal. Cranial nerve functions—diminished conjunctival and corneal sensibility on both sides. Paralysis of the facial nerve on both sides (infra-nuclear type). Loss of pharyngeal and palatal reflexes. Hoarseness of voice. Motor functions—complete paralysis of the muscles of the lower limbs; paresis of the muscles of the upper limbs; muscles flaccid; no wasting; co-ordination lost (as shown by the finger-nose test). Sensory functions—loss of sensation to light touch in both legs up to the middle of the thighs; hyperesthesia of the soles of the feet; joint sense in the fingers and

toes lost; astereognosis present. Reflexes—superficial: no response; knee and ankle jerks absent; biceps, triceps and supinator jerks sluggish. Sphincters—normal. Trophic changes—nil. Skull and vertebral column—normal. Respiratory, alimentary, cardiovascular and urinary systems—nothing abnormal. Laboratory finding—Wassermann reaction moderately positive. Patient was discharged on 27th May, 1935, almost completely cured but for a slight facial weakness of the right side.

Case 9.—B. L., Hindu, male, aged 37 years, was admitted on 8th November, 1938, with the complaint of loss of power of both lower and upper limbs for 8 days. General examination—build and nutrition moderate. Anaemia and jaundice—nil. Temperature 98°F., pulse 80, and respiration 20 per minute. Nervous system—higher cerebral functions unimpaired; sleep normal; speech normal; cranial nerve functions—unimpaired. Motor functions—paralysis of the muscles of the lower limbs; paresis of the muscles of the upper limbs. Sensory functions—slight blunting of sensation over the lower limbs. Reflexes—absent. Sphincters normal. Trophic changes—absent. Skull and vertebral column normal. Respiratory system—patient was reported to have respiratory difficulty before death. Alimentary system—spleen slightly enlarged. Cardiovascular and urinary systems—nothing abnormal. Laboratory findings—Blood: leucocytes 11,820 per c.m.m.; polymorphonuclears 68 per cent; a few M. T. rings and crescents found. Wassermann reaction of serum doubtful. Cerebro-spinal fluid was clear, 20 cells per c.m.m. (majority lymphocytes); Wassermann reaction strongly positive. Patient died of respiratory failure 3 days after admission on the 11th day of the disease.

Case 10.—M. M., Hindu male, aged 35 years, was admitted on 12th January, 1939, with the complaints of tingling and weakness in the upper and lower limbs. The weakness and tingling were first noticed in the upper limbs 8 days ago. General examination—build and nutrition moderate; jaundice and anaemia present; no cyanosis. Pulse/respiration 108/24. Nervous system—higher cerebral functions normal; sleep normal; speech normal. Cranial nerve functions—paresis of the right side of the face; no other abnormality. Motor functions—muscles of the upper and lower limbs paretic; no wasting; fibrillary twitching absent. Sensory functions—impairment of sensation to light touch over the distal parts of the upper and lower limbs. Reflexes—both superficial and deep reflexes absent; sphincters normal. Trophic changes—nil. Skull and vertebral column normal. Respiratory system—scattered râles in both lungs. Alimentary system—liver and spleen just palpable. Cardio-vascular system—nothing abnormal. Urinary system—nothing abnormal. Laboratory findings—Blood: haemoglobin 60 per cent; leucocytes 6,500 per c.m.m.; polymorphonuclears 60 per cent; Wassermann reaction negative. Patient developed paralysis of the diaphragm 4 days after admission and died on the 13th day of the illness.

Comments

A typical case of Landry's paralysis is characterized by (1) ascending flaccid paralysis unassociated with any wasting of muscles, (2) loss of tendon reflexes, (3) absence of sensory loss and sphincter disturbances and (4) absence of reaction of degeneration. A study of our cases however reveals that seven of them (cases 1, 3, 4, 7, 8, 9 and 10) presented one or more atypical features; thus case 1 showed wasting of the affected muscles with partial re-action of degeneration; case 3 showed some wasting of the paralysed muscles, as well as retention of urine though lasting for the first 3 days. Case 4 also showed some wasting of the affected muscles. In case 7 there was retention of urine and faeces for a few days. Moreover, a reaction

of degeneration was present in the muscles of lower limbs. In cases 8, 9 and 10 there was blunting of sensation to cotton-wool and pin-prick over the lower limbs. In case 8, there were in addition some loss of sensibility over the cornea and conjunctiva, astereognosis and loss of sense of position of the fingers and toes.

Further analysis reveals that there was some residual paralysis in one of the lower limbs in cases 7 and 3 even after 7 months and 2 years of convalescence respectively. The presence of a positive Wassermann reaction of the serum in case 8 and of a positive Wassermann reaction of the cerebro-spinal fluid in case 9 was a mere coincidence. A much more interesting finding is the presence of a few malignant tertian rings and crescents in case 9. It may be argued that in this case Landry's syndrome was caused by a malignant tertian infection and its concomitant embolic lesions of the spinal cord. But such a hypothesis was untenable because the patient was afebrile, quite conscious and his blood examination revealed both rings and crescents indicative of an old infection.

Summary

- (1) An attempt has been made to define Landry's paralysis.
- (2) Its aetiology and pathology have been briefly discussed.
- (3) The clinical picture of the condition has been described in detail on the basis of an analytical study of ten cases.
- (4) The prognosis and differential diagnosis have been dealt with.
- (5) Ten case notes have been appended.
- (6) The atypical features of Landry's paralysis have also been commented upon.

Acknowledgment

We take this opportunity to extend our grateful thanks to Lieut.-Colonel J. C. De, I.M.S., the Superintendent, Medical College Hospitals, Calcutta, and to Lieut.-Colonel B. H. Singh, I.M.S., the Superintendent, General Hospital, Howrah, for their kind permission to utilize the case records. Our thanks are also due to Dr. Amulya Ratan Roy and Dr. I. Ilias for much valuable assistance in collecting the case reports.

TREATMENT OF TUBERCULOSIS VERRUCOSA CUTIS BY LOCAL APPLICATION OF CREOSOTE AND SALICYLIC ACID

By D. PANJA, M.B. (Cal.)

(From the Medical Mycology Enquiry, under the Indian Research Fund Association, School of Tropical Medicine, Calcutta)

THE treatment of lupus vulgaris by the application of caustics has been a common method for many years. Among caustics two of the most popular are creosote and salicylic acid, either separately or in combination. Beatty (1928) treated 4 per cent of his cases of lupus vulgaris by pyrogallol ointment, acid nitrate of mercury, alkaline phenol and salicylic acid-creosote plaster. According to him the salicylic acid and creosote plaster acted well in some cases, but was slow. He, however, did not describe the variety of lupus vulgaris that responds best to this plaster.

During the last few years we have tried various caustics in treating different kinds of lupus vulgaris and we find that creosote and salicylic acid in paste form seems to give fairly good results in selected cases of lupus verrucosa. Lupus verrucosa, or tuberculosis verrucosa cutis, is characterized mainly by warty vegetations on an inflammatory base, affecting chiefly the extremities, the dorsum of the fingers and toes, the buttocks, and the thick skin of the palms and soles. The vegetations are more prominent in thick than in thin skins. It differs histo-pathologically from lupus vulgaris by the marked hyperkeratosis of the stratum corneum and predominant acanthosis of the prickle-cell layer, the tubercle with giant cells of the Langerhans' type being the same in both diseases (figure 1).

Creosote and salicylic acid paste does not give uniformly good result in all cases of tuberculosis verrucosa cutis; it varies in different stages of the disease as well as in different parts of the body. We are now able to classify the types of disease according to their response to the paste treatment.

Type 1.—Lesions on the thick skin of the palms and soles with well-marked vegetations (figure 7).

Type 2.—Lesions on the dorsum of fingers, toes and feet with hard heaped-up vegetations (figure 11).

Type 3.—Lesions on the other parts of the body, especially the extremities where the vegetations are not so hard and prominent (figure 9).

The cases belonging to type 1 gave the best response to the paste treatment; type 2 cases gave a less favourable result in big patches but were good in small isolated patches; while the third type of case did not improve much, as it was not possible for us to use the paste in its original form on the soft skin owing to the intense burning pain it caused.

The preparation of the paste and its method of application

The paste consists of three parts of creosote and two parts of salicylic acid which are mixed on a tile by means of a spatula.

The healthy skin round the lesion is first coated with vaseline for protection. A layer of the paste about a quarter of an inch thick is then applied on the lesion and kept exposed for 5 to 10 minutes, so that the creosote may soak into the vegetations and not spread on the surrounding skin, as it will do if bandaged at once. After this period the lesion with the paste is covered by a piece of oil-paper with cotton-wool on the top of it and tightly bandaged. The tight bandaging is very important as it forces the paste into close contact with the lesion. The dressing is kept for 48 to 72 hours. When it is removed, it is found that the entire group of warty vegetation has become brittle

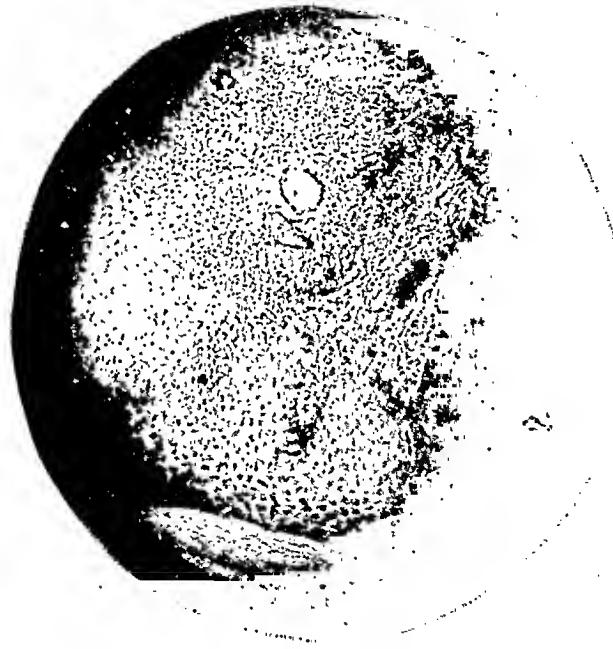

Fig. 1.—A photomicrograph of the section made from the biopsy material of one of our cases. This shows hyperkeratosis and marked acanthosis of the prickle-cell layer. At the base of the hypertrophied epidermis the changes are more prominent in the corium where there is cellular infiltration of the granulomatous type with the formation of tubercles containing giant cells of various sizes.

and can be removed easily with a pair of dissecting forceps, and a red clean ulcer is left. The ulcer heals up rapidly with a dressing of borovaseline only and without secondary complication except scarring. In lesions on the fingers and toes where the bone is close to the skin, healing takes a long time and a bad scar is left behind. In some cases, a second or even a third application is necessary.

Modification of the above method of treatment

In the third type of case, where the original paste of creosote and salicylic acid was not

suitable for local application owing to the intense burning pain and troublesome ulceration it caused, a modified paste diluted with glycerine was used according to the following formula :—

Creosote 2 parts.
Acid salicylic 2 "
Glycerine 4 "

The cases respond to this modified treatment if it is continued for a long time. In a few cases of lupus vulgaris this therapy was tried but to no effect; on the contrary most of the patients did not come back probably because of the intense pain.

In addition to the usual treatment with the paste, the general health of the patient should be improved by tonics.

A few cases exemplifying the paste treatment are given :—

Case 1.—A Hindu male, aged 27 years, cultivator by occupation, developed the lesion two years ago as a tiny nodule which gradually extended to the present size (figure 2).

There was a mild and slightly painful warty excrescence with a few small depressed scars due to healing of small abscesses, a characteristic feature of the lupus verrucosa. The creosote and salicylic acid paste was applied and it was removed after 72 hours, when the entire vegetations with a little healthy surrounding skin came off leaving a red raw ulcer (figure 3). This ulcer healed up within a fortnight with a dressing of borovaseline only (figure 4).

Case 2.—A Mohammedan male, aged 31 years, working as a mill-hand in a jute mill, developed the disease three years ago; the lesion covered the middle third of the sole of the left foot. The creosote and salicylic acid paste was applied and the slough formed thereby was removed after 48 hours when a clean ulcer was formed (figure 5). This ulcer rapidly healed with a simple borovaseline dressing; but a portion of the tuberculous lesion still remained unaffected (figure 6). Here a second application of the paste was necessary.

Case 3.—A Hindu male, aged 24 years, working in the railway as a fitter, had been suffering from the disease for the last ten years. At the present stage, it is extensive with heaped-up warty excrescences covering more than one-third of the sole of the left foot (figure 7). A thick layer of the creosote and salicylic acid paste was applied and though the patient felt more pain than that of the previous patients the result was very encouraging. The entire warty vegetations were removed still leaving some tuberculous material at the margin (figure 8). In this case a second and a third application of the paste was necessary.

Fig. 2.

Fig. 3.

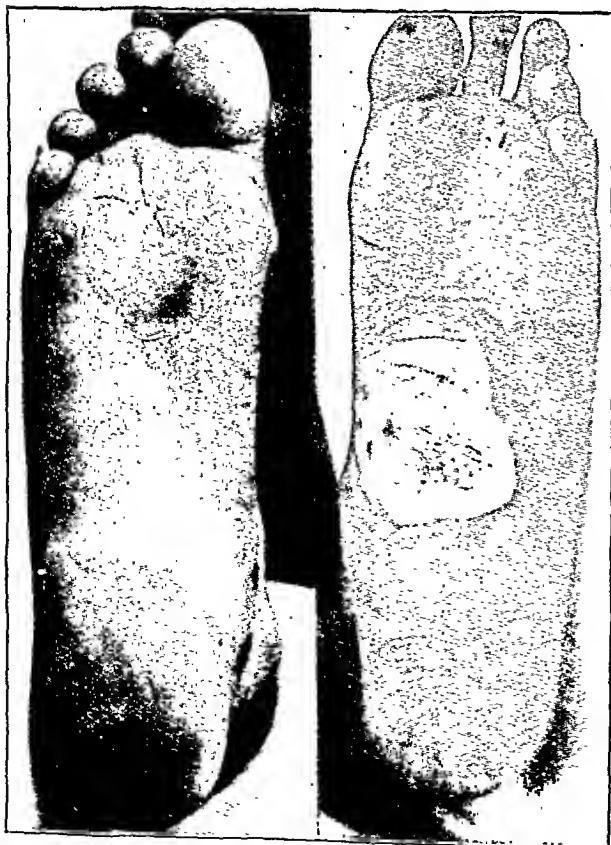

Fig. 4.

Fig. 5.

Fig. 6.

Case 4.—A Hindu boy, aged 12 years, had the disease on the dorsum of the right foot for more than one year. There were soft warty excrescences about the size of a rupee (figure 9). The paste was applied and the redundant warty growth came off within 48 hours

Fig. 7.

Fig. 8.

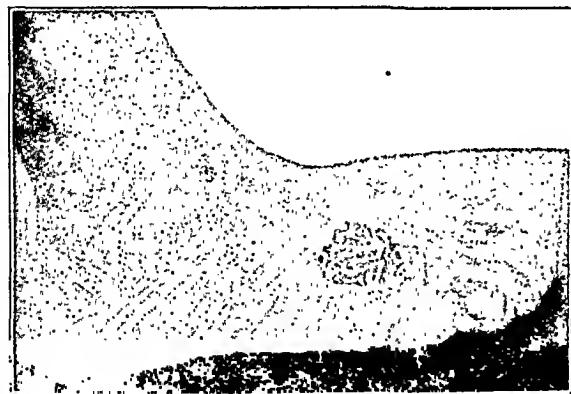

Fig. 9.

leaving a small diseased area (figure 10), which did not respond to the second application and the patient refused a third application owing to the pain he experienced on the second occasion.

Figure 11 shows how the dorsum of finger is affected with the disease, showing typical warty excrescences.

Discussion

These two chemicals, salicylic acid and creosote, possibly exert a selective action on the disease which may be explained as follows:—

The former softens the hard and thickened vegetations of the stratum corneum, thereby allowing the creosote to penetrate into the

PRE-AURICULAR FISTULÆ

By MANMOHAN NATH KHANNA F.R.C.S. (Eng.),
F.R.C.S. (Edin.)

Honorary Surgeon, Sir Gangaram Hospital, and
Isharadas Kapur Hospital, Lahore

This subject was brought to the notice of the medical profession in Britain first by Sir James Paget in the year 1878. Then, Sir Arthur Keith demonstrated some specimens in the museum of the Royal College of Surgeons, and published papers in 1909. Later, papers were published by Evans (1910), Fournier (1919), Paget and Rugani, Pritchard; and lastly by Stammers in 1926. The last author has brought the subject up to date, and has been freely quoted.

This condition, which is a congenital anomaly, may manifest itself as a dimple, sinus, fistula, abscess, chronic ulcer, dermoid, auricular appendage, or an ugly scar situated in front of the ear. Usually, they are unilateral, but

(Continued from previous column)

tubercle where it destroys the bacilli. So this remedy has two advantages, one is the mechanical removal of the pathological tissues by the salicylic acid and the other is the destruction of

Fig. 10.

Fig. 11.

bacilli by the creosote. The disadvantages of pain and discomfort for 48 to 72 hours during which the paste is on can usually be tolerated by intelligent patients who are anxious to be free from a chronic troublesome disease.

REFERENCE

BEATTY, J. (1928) ... *Brit. Med. J., i*, 47.

occasionally may be bilateral (as in one of my cases). Stammers has laid great stress on the condition being familial and hereditary, but that claim could not be substantiated in my cases. The condition is not very common, but at the same time is not very rare. I have come across seven cases during the past sixteen months; of these one had three sinuses and a big scar; two had one sinus and an ulcer each; and four had one sinus each without any complications.

Situation.—The opening of the sinus may be present at the junction of any two of the six tubercles which go to form the pinna, but it has been seen that the most common sites are the crus helix and the tragus.

History.—The usual history of the case is very typical and characteristic. The child is born with a dimple in one of the sites mentioned above. Unfortunately, in our country, some people attach a religious significance to such congenital defects. The parents consider it a good omen, because such a baby is believed to be a born 'Yogi' (the well-known Kanphata-Yogi, that is, a Yogi with torn ears)—the more so if the condition is bilateral. This dimple is the external orifice of the track which is superficial in character, lined with the skin epithelium, is directed downwards and forwards, but does not involve the bone. For a few years the track remains clean, but later on some thick greyish-white foul-smelling discharge can be pressed out. This is only the secretion of the epithelium lining the track, which sometimes becomes inspissated. The mouth of the track may become

blocked by the secretions drying up, causing discomfort and swelling of the part behind. The plug may dislodge itself or may be removed by thoroughly washing the part with soap and water giving relief to the patient. But sometimes, through want of proper cleanliness, or accidentally, infection supervenes and an abscess is formed. This is treated on general lines. Either it opens by itself or is opened by the knife. The fistula forms and later may temporarily close, but

Fig. 1.—Showing the right side of the face of case 1.

1. Scar in front of the ear.
2. Opening of the sinus at the crus helix.
3. Opening of the sinus in front of the tragus.

re-opens after a few days. This state of affairs goes on for a long time, and to the great astonishment and disgust of the medical attendant the fistula refuses to heal. The constant irritation by the secretion leads to ulceration, which goes on spreading and causing great

discomfort and disfigurement of the patient's face. These patients usually wander from place to place and try to obtain relief through any system of medicine; the unqualified, the untrained, and the quacks being consulted most, because they claim to produce miracles. Thus, the treatment is carried out empirically and symptomatically without removing the root cause of the trouble. When, however, the correct diagnosis is made the treatment becomes simple, sure, and rapid.

Diagnosis.—Knowledge of the development and the anatomy of the part should guide one to the correct diagnosis. The condition is so obvious that it should never be missed if one knows what to look for. A lump or a chronic ulcer in front of the ear should always remind one of the presence of the pre-auricular sinus underlying the condition. One should always look for the tiny opening in one of the sites described above. It is only when careful examination fails to reveal the presence of any congenital defect that one should proceed to look for some of the other causes of the condition, such as sebaceous cyst, dermoid, lipoma, osteomyelitis of the zygoma, tubercle, syphilis, etc., etc.

Treatment.—This consists in thoroughly excising the whole track in one mass, and endeavour should be made to include the ulcer base also. Cauterization of the track has been tried, but the results have not been very encouraging, as there is always a chance of leaving behind small bits of the epithelium, which may be responsible for keeping up the condition. Cold steel knife is decidedly better than the cautery.

Incidence.—Of all the cases coming up for examination Eyle found the condition present in 0.26 per cent, Bezold and Urbantschitsch in 0.19 per cent, while Rugani got much higher figures. I have seen seven cases out of about 6,800, in

Fig. 2.—Showing the left side of the face of case 1. Opening of the sinus at the crus helix.

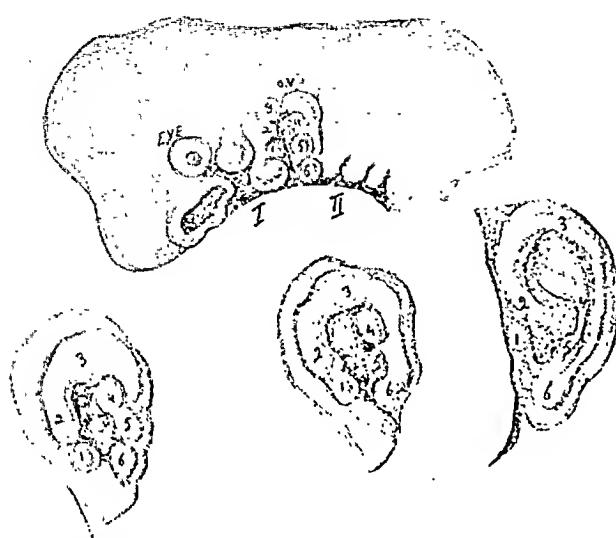

Fig. 3.—Showing the right side of the face of case 2.
1. Opening of the sinus at the crus helix.
2. Ulcer in front of the ear.

the past sixteen months. Of these 7 cases, the following three are described in detail, because they had some complications :—

Case 1.—A boy, 5 years old, poorly developed. At the age of 2 years, he developed an abscess in front of the right ear, which was opened. The sinus persisted for about 3 years, and a big ulcer was formed; it was treated at various places by ointments, lotions, etc., but the relief was always temporary.

- 1. Tragus.
- 2. Crus helix.
- 3. Helix.
- 4. Antihelix.
- 5. Antitragus.
- 6. Lobule.

Examination.—A small pin-point opening at the root of the helix on both sides. A lachrymal probe could be passed in it for 2.5 cm. downwards and forwards. There was no pain, tenderness or any discharge, not even on pressure. Owing to the bilateral nature of the lesion, the child was considered a Yogi.

A small pin-point opening 0.75 cm. in front of the tragus of the right ear. A lachrymal probe could be passed in it for 3 cm. There was no pain, tenderness, or discharge, not even on pressure, but the father of the child said that at times thick, greyish-white discharge could be pressed out.

A large circular scar in front of the right ear, 4.5 cm. in diameter. In this scar, the second (*v.s.*) opening was situated.

X-ray examination of the part did not reveal any evidence of bony lesion.

Case 2.—A girl, 3½ years old, in fairly good health. At the age of 2½ years, a lump appeared in front of the right ear, was treated by various remedies, ointments, lotions, fomentations, etc., but the condition did not respond to treatment. Eight months later, she was operated on, even that did not give any relief.

Examination.—A pin-point opening at the root of helix of the right ear. A lachrymal probe could be passed in it for 2½ cm., downwards and forwards. It emerged out at the base of the ulcer (*v.i.*) through a small opening. Saline injected through the opening by means of a hypodermic needle and syringe came out through the ulcer base.

A chronic ulcer in front of the right ear, 4 × 3½ cm., irregular in outline; base hard and fixed to the underlying tissues; surface covered with unhealthy

granulations—pale, anaemic, and bleeding readily on touching; edges very irregular, pale, and in some places undermined, and there was a profuse foul discharge from it.

Case 3.—A girl, 6 years old, poorly nourished. At the age of 2½ years she developed an abscess in front of the left ear, which burst under treatment; later, an ulcer was formed which has not responded to any treatment; she has been operated on four times at different places. Now she suffers considerably from the pain and foul smell.

Examination.—A pin-point opening at the root of the helix of the left ear. A lachrymal probe could be passed in it for 4 cm. downwards and forwards. It emerges at the base of the ulcer (*v.i.*) through a small opening.

A chronic large ulcer in front of the left ear 5 × 4 cm., irregular in outline, base hard and fixed, surface trabeculated and pale unhealthy granulations in between which readily bleed, edges irregular, and there is profuse discharge from it.

Treatment.—Treatment in all cases was the same. Hypertonic (10 per cent) saline compresses 4 hourly were applied for 3 to 7 days until the surface became clean. Then the track was excised in one mass including the ulcer with it. Under the base of the ulcer, thick hard fibro-cartilaginous tissue was found, which was removed. Silkworm-gut stiches were applied, and it was found that everything healed by first intention, except a small part of the ulcer in case 3, which took 5 days more to heal. So the results in all my cases have been very encouraging.

Discussion.—In order to understand fully the nature and the origin of these sinuses, fistulae, and ulcers, one must go into the development of the parts, and the various theories which go to explain their origin.

Development.—The external auditory meatus and the concha are developed from the first branchial cleft, and the pinna from the six tubercles situated around the posterior end of this cleft, two being in the first arch, three in the second, and the remaining one at the junction of the two. These six tubercles are destined to form the tragus, crus helix, helix, antihelix, antitragus, and the lobule, respectively. The part that forms the external auditory meatus lies between the tubercles nos. 1 and 2, in front, and the tubercles nos. 4, 5 and 6 behind, and any defect or deformity resulting from the remains of the first cleft will lie between the tragus in front and the lobule behind, and will, moreover, communicate with the concha and the external auditory meatus.

During coalescence of the six tubercles, tiny subcutaneous tracks may be left over. The fistulae of this series of cases are developed mostly in the area of coalescence of tubercles nos. 1 and 2; and most of the sinuses occur in the region of the crus helix and the tragus. The downward and forward direction of the fistulae can be explained by the downward and forward development of the mandibular arch with its maxillary process.

The auricular appendage, which is not infrequently noticed, is a process most commonly derived from a subdivision of the tragus. There

is evidently a relationship between the auricular appendages and the fistulae, for it was noted by Sir Arthur Keith that one of the commonest sites for their occurrence is in front of the ascending root of the helix, the point at which a depression or fistula would be formed if a pre-helical appendage becomes submerged during development. The fistula which is found on the ascending helix occurs at the point where the two tubercles fuse together to form the anterior or the mandibular part of the helix. When one remembers that the external ear is formed out of six tubercles which fuse together across the first cleft, one wonders why gaps and fistulae are not of more common occurrence.

Theories of origin.—1. Fistula is the remains of the first branchial cleft.

The formation of the sinus must be between the tragus in front and the lobule behind, and it must extend into the external auditory meatus and the concha. The majority of the old textbooks and some authorities, such as Virchow, Schwartz, and Urbantschitsch, favoured this view; but others, for example, His, Gradenigo, Rugani, and Brash, are of the opinion that there is no connection between the fistulae and the first branchial cleft.

2. Failure of union of the soft parts corresponding to, and overlying the posterior ends of, the mandibular and maxillary processes of the first branchial arch.

According to this, such fistulae are the posterior end of a macrostoma, though the anterior end is normal, so that no actual macrostoma is present, the soft parts overlying the posterior end of the mandibular bar and its maxillary process have just failed to unite. This theory explains the direction of the fistulae. But even in its severest form a macrostoma never extends quite so far back as the ear. The bony parts unite all through, but the soft parts may fail to unite in the posterior part, forming a small sinus.

3. Failure of union between some two of the six tubercles, which appear around the posterior end of the first branchial cleft, and which go to form the pinna, or some anomalous process occurring in connection with these tubercles.

This is the most favoured theory. Most of the fistulae are situated at the root of the helix or in front of the trugs; the sinus is superficial, lined with skin epithelium, and the bone is not involved.

From the above it would appear that theory no. 1 does not help us at all to explain the formation of these fistulae. Theories nos. 2 and 3 seem to have a great deal of truth in them, though each one alone cannot explain all the factors. A combination of both would be a more plausible explanation. The direction of the sinuses is best explained by theory no. 2, whereas the site is more in favour of the theory no. 3.

Summary.—1. Pre-auricular sinuses and fistulae are not infrequent. Seven cases are

KAPOSI'S DISEASE

By FRANKLYN V. STONHAM

CAPTAIN, I.M.S.

Civil Surgeon

and

D. C. NAGPAUL, P.C.M.S.

Assistant Surgeon, Dera Ghazi Khan, Punjab

THREE cases of this extraordinary condition recently came under observation. The affection was first described by Moriz Kaposi and given the name of xeroderma pigmentosum*. A large number of other names have been given, examples of which are atrophoderma pigmentosum (Crocker), melanosis lenticularis progressiva (Pick), and lioderma cum melanosi et telangiectasia (Neisser). Since these names are somewhat cumbersome and are not quite accurate from a descriptive standpoint, the association of Kaposi's name might well be retained, and, though the clinical features of the cases observed in patients living under tropical conditions appear to differ in important respects from those seen in Europe, Kaposi's (1895) description may with advantage be quoted :

'The face, ears, neck, shoulders, the chest to the level of the third rib, the arms and backs of the hands, sometimes the dorsal surfaces of the feet, are dotted with larger and smaller yellowish brown patches like freckles. Between these are found pock-like, whitish, glistening, shallow depressions, or the integument has a normal colour. The variegated appearance of

* The etymologically-more-correct name 'xeroderma pigmentosa' is used in the *British Encyclopaedia of Medical Practice*. The disease is not very rare in Calcutta: a dozen cases or so have been treated at the skin clinic of the Calcutta School of Tropical Medicine during as many years; they usually turn up in batches, two or three members of the same family.—Editor, J. M. G.

(Continued from previous column)

reported, of which three were complicated, and have been described in detail.

2. History of the cases do not show any familial or hereditary tendency.

3. Prognosis is very good under proper treatment.

4. Treatment consists of complete excision of the track.

5. The exact mode of formation is uncertain, no single theory being enough to explain all the factors.

In conclusion, my thanks are due to the medical superintendents of Sir Gangaram hospital and Ishardas Kapur hospital, for kindly allowing me to publish these notes.

the skin is intensified by numerous punctate or linear telangiectases. The epidermis is thin, in places smooth, and in other places it is detached in thin lamellæ, or finely furrowed, fissured, wrinkled, dry like parchment. The cutis itself feels thin, but often, when the disease has lasted for some time, it is with difficulty raised into folds; it is more firmly adherent to the underlying tissues and is poor in fat. The general integument of the rest of the body is normal in every respect. So far as we can learn the disease always begins in earliest childhood and progresses steadily. Small telangiectases and pigment patches first develop; then the vessels are almost entirely obliterated and corresponding achromatic whitish glistening atrophic depressions are left over. Later, there is diffuse shrinking of the skin, above which the epidermis becomes wrinkled and is detached in lamellæ. The increasing shrinking of the skin is followed by eczema, shallow rhagades and ulcers, narrowing of the mouth and nares, and ectropion of the lower lids (this gives rise occasionally to xerosis of the cornea). In the majority of cases (five times among my ten cases) carcinoma, sarcoma, or angioma has developed in a few months upon scattered parts of the face, lips, nose, lids, cheeks and concha of the ear. In two cases internal metastases developed with fatal termination.

The disease in India.—The cases observed were amongst the indigenous population who normally possess a greater or less degree of pigmentation, though in the Punjab where these examples were observed the skins are comparatively fair, and what is termed locally a 'wheat-coloured' complexion. All the cases reported for treatment for ophthalmological reasons. The appearance was very striking. The whole skin except the palms and soles was covered with fine dark spots varying in size from that of a pin-point to that of a match head. The lesions were most numerous on the face, but otherwise the distribution closely followed that given above. The faces all had a very black appearance, and this caused the sufferers to be very conspicuous. The skin looked as though it had been liberally sprayed with black paint by means of a paint sprayer. The colour varied from brownish black to jet black. Pigmentation occurred on the mucosa of the lips and faded out just inside the mouth. Lighter brownish irregular patches occurred in the conjunctiva around the limbus, but other mucous membranes appeared to be free from pigmentation. Telangiectasis was noted, but was not a prominent feature, except in one case. Neither were scalliness nor atrophic conditions at all prominent, but some atrophy was observed between the pigmented spots on the face. All the patients were practically blind, and this was due to what appeared to be a true keratitis of all the layers of the cornea. All the corneaæ were white and opaque throughout, though the opacity was somewhat uneven. A few irregular blood vessels passed in from the periphery. Ulceration was noted but was inconspicuous and out of proportion to the degree of opacity, and this suggested that the changes probably depended on impaired nutrition. The lids were slightly thickened, but showed no deformity.

The condition appears to be associated with a striking tendency to malignancy. Out of three cases one had a melanoma of the eye and the

other a parotid tumour. The subjects were all of fair physical development and showed no evidence of any associated disease. There appeared to be no connection with syphilis, leprosy or malaria, and the eye lesions did not appear to be associated with trachoma which is very common in the locality.

Aetiology.—The disease is probably due to a congenital anomaly of the development of the papillary stratum, with associated defects in nutrition. Microscopic examination shows masses of pigment granules irregularly arranged in not only the superficial layers, but in the corium as well. It should be noted that a normal Indian skin contains no pigment in the corium. Some atrophy of the papillary layer is evident, but the prolongation of papillary pegs into the dermis and ectasia of the glands described by Kaposi was not observed. There were no significant changes in the blood films.

Case 1.—Mohammedan Jat female, aged 1½ years. The child was well built and active. The disease was first noted 4 months previously. The skin was covered with black spots and rosy telangiectases most numerous on the face, but otherwise on the whole body except the palms and soles, with a tendency to increased distribution on the neck, back, chest, shoulders and upper arms. The black spots were punctate and not raised but tended to be of larger size on the face. The right cornea was distinctly opaque, and the left was sufficiently hazy to prevent examination of the fundus. The child constantly squeezed the eyes, but appeared to have some useful vision. She had a tendency to hold the head to the left. The Wassermann test was negative and the blood showed no evidence of malaria and a normal cell count. No evidence of disease was detected in other systems.

Case 2.—Mohammedan Jat male, aged 3 years, brother of case 1. The condition was first noted 18 months previously. Fine black pigmentation covered the whole body except the palms and soles. It was very marked on the face and ears, and well marked on the upper part of the chest and back, neck, arms and thighs. Many of the spots on the face were the size of a match head or larger, though mostly not raised above the skin. Both corneaæ were opaque and ulcerated and the child appeared to have perception of light only. There was a suggestion of proptosis of the right eye. There was weakness of the right facial musculature, and weakness of the left arm and leg. A tender nodule was observed in the right parotid gland and the mouth could not be widely opened. The blood showed a normal cell count, no malarial parasites, and a negative Wassermann test. Both eyelids were kept partly closed, though the lids themselves appeared healthy; other systems were normal and the child seemed intelligent. Exploration was refused.

Case 3.—J. U., Mohammedan Jat male, aged 18 years, of good physical development. Disease commenced in childhood. No family history of similar disease was obtained. Patient had two healthy brothers and one sister. The whole body except the palms and soles was covered with fine black or brownish black spots, mainly punctate, but up to the size of a match head. None were raised above the surface. The maximum distribution was seen on the face, but the shoulders, neck, upper parts of the chest and back, and the arms, especially the sides of the upper arms were heavily pigmented. The left cornea was opaque and the patient could see large moving objects only and the right cornea was replaced by a purplish fleshy tongue-like process, which projected between the lids. The right eye was excised and the tumour proved to be a melanoma, and black pigmentation was visible.

THYROID DRUGGING IN GRAVES' DISEASE

By R. N. CHAUDHURI, M.B. (Cal.), M.R.C.P. (Edin.),
T.D.B. (Wales)

(From the Tropical Medicine Department, School of
Tropical Medicine, Calcutta)

GOITRE cases require full study and careful assessment before the line of treatment can be decided upon. Greatest caution should be taken while administering drugs like iodine and thyroid extract in these cases, for these drugs may serve as exciting causes of Graves' disease

(Continued from previous page)

to the naked eye when the tumour was incised. Wassermann test was negative and blood cells normal and free from parasites.

A strange feature of this 'disease' is the tendency to occur in members of the same family, though it does not appear to be hereditary. Sequeira (1915) quotes an instance in which seven children in one family suffered from it. The cause is unknown and the reason for the tendency to malignancy is obscure. The influence of sunlight has been suggested as the cause, but this is not universally accepted. We are not aware that the incidence is higher in the tropics. The cases described all lived in a hot dry climate where the summer temperature ranges from 110°F. to 125°F. or more for several months. The prognosis is hopeless as most of the patients die in childhood or early adult life, usually from malignant disease.

Since the pathology of the condition is not understood, no rational treatment can be devised which might influence its progress. In the cases which came under our observation large doses of nicotinic acid and ascorbic acid were injected because the conventional diet in the district was known to be deficient in vitamins B and C. This was combined with arsenic, cod-liver oil, and hypophosphites together with oily applications to the skin. No effect whatever was observed. The treatment therefore can only be purely symptomatic and directed to preventing or arresting ophthalmic complications and prompt removal of malignancies as they appear.

Summary

(1) Three cases of xeroderma pigmentosum are described.

(2) The differences between the disease as it occurs in eastern races and Europeans is pointed out.

(3) Until the aetiology and pathology of the affection are understood, the affection presents a hopeless problem.

in susceptible persons. In these circumstances, they may appear to serve the same function aetiologically as psychic trauma—the torch starting the conflagration in an inflammable subject. Cases have been recorded in which Graves' disease occurred shortly after the use of thyroid tablets taken for the purpose of overcoming obesity, or for an already existing slight hyperplasia of the thyroid, mistaken for simple compensatory enlargement. The following case of indiscriminate administration of thyroid tablets in a thyrotoxic subject leading to aggravation of the condition is reported :—

An Anglo-Indian married woman, 39 years of age, was admitted on the 27th July, 1940, exhibiting the typical signs of primary Graves' disease. The onset of symptoms was sudden. She was quite well until February the 16th, when she noticed the swelling in the neck for the first time. She herself thought it to be goitre, got very worried, and visited a doctor on the following day; he confirmed her diagnosis and prescribed a mixture, one ingredient of which was iodine, and thyroid tablets—one (she did not know the exact dose) to be taken daily before retiring. He also advised her to take simple food. She consulted him again on the 19th; her weight had gone down by five pounds in three days; she was then advised to take two tablets of thyroid daily. Next, she saw him on the 22nd; there was further reduction in weight and tablets were now increased to three a day. Her next visit was on the 27th; the weight dropped still further. She was given two bottles of medicine, and the tablets were increased to four a day. Her subsequent visit was on the 6th March, when the tablets were increased to five daily along with two bottles of medicine; this was continued till the 17th.

As she felt worse from day to day, lost weight progressively and felt very nervous and tremulous, while the goitre grew bigger, she discontinued the treatment and later consulted another doctor who prescribed Lugol's iodine and a bromide mixture. She felt a little better with this treatment, but the progress was rather slow.

Subsequently she consulted a doctor friend, who also prescribed Lugol's iodine. She took it for some time, but later she used to get sick with it and could hardly retain it. He then removed her to his own residence, kept her in bed, and consulted another doctor who prescribed a belladonna and bromide mixture. She picked up considerably and then returned to her own place and resumed household duties. Soon after she had a set-back and therefore sought admission into the Carmichael Hospital for Tropical Diseases.

On admission the patient complained of palpitation, nervousness, great loss of weight, disturbed sleep, fatigue, occasional diarrhoea, poor appetite, bulging eyes and goitre. She was carefully interrogated, but no psychic trauma could be elicited as the precipitating factor.

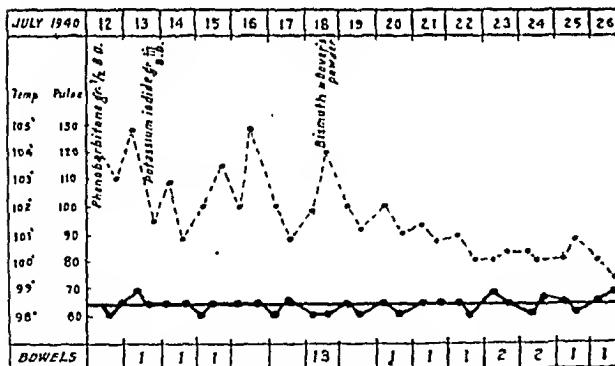

There was nothing particular with regard to her family and personal history.

Physical examination.—A thin under-nourished woman with a staring look; an average degree of exophthalmos with indefinite eye signs of Graves' syndrome; moderate-sized thyroid enlargement (maximum circumference of the neck— $13\frac{1}{2}$ inches) with smooth surface and definite systolic bruit; a rather excitable heart with a pulmonary systolic bruit; a collapsing type of pulse with a regular rate of 120 per minute; markedly pulsating abdominal aorta; fine tremor of the tongue and out-stretched fingers and moist warm palm. Her weight was 132 pounds; she had lost four stone in five months. The blood pressure was systolic 125 and diastolic 55 mm. of Hg., with a pulse pressure of 70. Following Read's formula— 0.75 (pulse rate + $0.74 \times$ pulse pressure)—72—the basal metabolic rate was plus 56.8 per cent. The B. M. R. actually estimated by the Benedict-Roth metabolism apparatus was plus 50 per cent.

Blood count.—Hæmoglobin 68 per cent = 9.35 grammes per 100 c.c.m.; reticulocytes—0.2 per cent; red cells—3,620,000 per c.mm.; cell volume—30 per cent; mean corpuscular volume 83.3 cu μ ; mean corpuscular hæmoglobin 25.9 $\gamma\gamma$; mean corpuscular hæmoglobin concentration 31 per cent; leucocytes—6,000 per c.mm.; polymorphonuclears—34 per cent; lymphocytes—55 per cent; large mononuclears—6 per cent; and eosinophils 5 per cent.

Van den Bergh test—negative.

Other laboratory findings are not relevant.

Treatment.—The patient was at once made a bed-case and put on phenobarbitone, grain $\frac{1}{2}$ twice a day. Next day she was given potassium iodide, grains iii twice a day along with a high calorie diet. The iodide did not upset her in any way. After about a week while she was beginning to settle down, it was suggested that she might require an operation. This was enough to upset her nerves and caused severe diarrhoea—thirteen watery stools in twenty-four hours, which was readily controlled with two doses of bismuth and Dover's powder. The condition gradually improved and pulse came down to 72 per minute on the 15th day

SULPHATHIAZOLE IN SOME EXPERIMENTAL BACTERIAL AND VIRUS INFECTIONS

By R. SANJIVA RAO, M.B., B.S. (Mad.),
D.T.M. (L'pool)

and

K. GANAPATHI, M.Sc. (Mad.)
(From the Haffkine Institute, Bombay)

THIS paper presents the results of testing sulphathiazole in experimental *Bacterium typhosum*, *Vibrio cholerae* and fixed-virus infections in mice, and vaccinia-virus infection in

(Continued from previous column)

although she had further lost in weight. Subsequently she agreed to be operated upon and was transferred to the surgeon for preparatory treatment and thyroidectomy.

Summary and discussion

A woman, apparently with Graves' constitution, accidentally discovered one day that her thyroid was swollen. There was no obvious evidence of general or focal infection, or nervous shock that is usually regarded as the provocative factor in the causation of Graves' disease.

It is possible, there might have been psychic trauma which was difficult for the patient to recall to memory; or it might have been that she had undergone such a trauma but that its nature was distasteful to narrate. In the absence of careful psycho-analysis by experts no further light could be thrown on the subject.

Very likely the patient had the thyroid hyperplasia for some time before she happened to discover it, and she was obviously sensitive to the effects of thyroid, so that the condition was aggravated to a marked thyrotoxic state by its injudicious administration in increasing doses.

Discontinuation of the drug and treatment with rest, Lugol's iodine and sedatives improved her condition, but later she used to get sick with the iodine solution.

During a subsequent exacerbation she was admitted in the Carmichael Hospital for Tropical Diseases. The clinical picture has been described and the result of basal metabolic rate, as determined by Read's formula as well as gasometric method given. Blood count showed an increase in the percentage of lymphocytes.

Treatment consisted of bed-rest, potassium iodide in small doses (this was well tolerated by the patient), phenobarbitone and high calorie diet. The progress was satisfactory, and there was a steady improvement except one attack of typical nervous diarrhoea of thyrotoxic origin.

She was subsequently handed over to the surgeon.

Acknowledgment

My grateful thanks are due to Dr. L. E. Napier for his kind permission to publish this note and for valuable suggestions.

rabbits. For comparative study sulphanilamide and sulphapyridine were also tested in some infections.

Bact. typhosum

A strain isolated from blood of a severe case of typhoid was used. This organism, immediately after isolation, was not found to be very virulent for mice. After nine passages in mice it gained considerable virulence; 100 million organisms given intra-peritoneally produced death in 24 hours. The mice used in the experiments were of the Haffkine Institute in-bred strain, 6 weeks old, and weighing between 15 and 20 grammes. Older mice were found to be less susceptible to infection. For purposes of experiment, 100 million organisms from a 17-hour-old culture of the organism in ordinary nutrient broth were injected intra-peritoneally into mice. The drug under test was made into an emulsion in gum acacia so that 0.5 c.cm. of this emulsion contained the required amount of the drug. This quantity was fed to the mouse by means of a glass pipette introduced into its stomach. The results are shown in table I.

TABLE I

The therapeutic effect of sulphanilamide, sulphapyridine and sulphathiazole in experimental *Bact. typhosum* infection in mice. The drugs were administered in 20 mg. doses soon after infection, 10 hours later and then twice daily for 3 more days

Drug administered	Number of mice out of a group of 16 dying on each day after infection						Survivors	Average survival time (days: max. 10)
	1	2	3	4	5	6-10		
Sulphanilamide	4	12	7.5
Sulphapyridine	3	2	11	7.3
Sulphathiazole	2	1	..	2	11	7.3
Controls	..	16	0	0.0

V. cholerae

An Inaba strain of *V. cholerae* was passed serially through 6-weeks-old mice until it was found to have acquired sufficient virulence for

mice. It was found that after eleven passages about 875 million vibrios killed mice in 24 hours. Further passages however did not enhance the virulence. For purposes of experiment 875 million vibrios from a 17-hour-old culture were injected intra-peritoneally into 6-weeks-old mice. The drug was administered as in the experiment with *Bact. typhosum*. The results are shown in table II.

TABLE II

The therapeutic effect of sulphanilamide, sulphapyridine and sulphathiazole in experimental *V. cholerae* infection in mice. The drugs were administered in 30 mg. doses soon after infection and 10 hours later

Drug administered	Number of mice out of a group of 12 dying on each day after infection						Survivors
	1	2	3	4	5	6-10	
Sulphanilamide	12	0
Sulphapyridine	12	0
Sulphathiazole	12	0
Controls	..	12	0

Bacteriostatic effect on *V. cholerae*

In view of the absolute lack of therapeutic effect of the drug in *V. cholerae* infection, an 'in vitro' test was put up to ascertain if the drug possessed any bacteriostatic properties in relation to *V. cholerae*. A test with sulphanilamide was also put up for comparison. The results are shown in table III.

Fixed rabies virus

The strain of fixed rabies virus (Paris strain) used in the routine manufacture of antirabic vaccine in this institute was used for purposes of infection. Three-weeks-old mice were used as they give uniform results. The minimum infective dose of the virus as determined by the method of Webster (1939) was 0.03 c.cm. of 1/160 dilution of the virus. The virus was diluted in 10 per cent horse serum in distilled water and 0.03 c.cm. of a 1/40 (representing four

TABLE III
Bacteriostatic action of sulphanilamide and sulphathiazole on *V. cholerae*

Drug	Number of organisms inoculated per c.cm.	Number of hours that elapsed between inoculation and appearance of growth in the various dilutions of the drug				
		1-2,500	1-5,000	1-10,000	1-20,000	1-30,000
Sulphanilamide	{ 500	48	24	24	24	24
	5,000	48	24	24	24	24
Sulphathiazole	{ 500	168	144
	5,000	Not tried	Not tried	120	96	48
Sulphathiazole + para-aminobenzoic acid	5,000	24	24	24	24	24

minimum infective doses) dilution of the virus was injected intramuscularly into the lower third of the gastrocnemius muscle of the mouse. Sulphathiazole was administered as in the previous experiments. The result was a complete failure of the drug in checking the fixed virus infection. All the mice died within 15 days of paralysis.

Vaccinia virus

Vaccine lymph obtained from the vaccine lymph institute at Belgaum and white rabbits weighing between 1.25 and 1.5 kg. were used in these experiments. The backs of the rabbits were shaved and about 0.1 c.cm. of vaccine lymph was smeared over the shaved surface which was then lightly 'scarified'. The drug was administered to one rabbit by mouth. Two received the solution of sodium salt of the drug parenterally and two served as controls. The results are shown in table IV.

TABLE IV

The therapeutic effect of sulphathiazole in vaccinia virus infection in rabbit

Weight of rabbit	Mode of treatment	Result
1.34 kg.	1 g. by mouth twice daily for 3 days.	Moderate 'take' after 72 hours.
1.32 kg.	0.375 g. (Na salt) intramuscularly twice daily for 3 days.	Do.
1.35 kg.	Do.	Do.
1.48 kg.	Control—not treated	Typical 'take' in 72 hours.
1.52 kg.	Do.	Do.

Discussion

Buttle *et al.* (1937) first reported that sulphanilamide, administered immediately after infection in single or repeated doses of 25 mg. protected a large percentage of mice against a moderate infecting dose of *Bact. typhosum*. Powell and Chen (1939) found that sulphanilamide in two doses of 5 mg. gave a good protection against 10 to 100 lethal doses of *Bact. typhosum*, while sulphapyridine under the same conditions gave inferior results. Kolmer and Rule (1939), who injected the above two drugs in doses of 0.160 g. per kg. body-weight, obtained only poor results, sulphapyridine being a little inferior to sulphanilamide. In our experiments (table I) there was no significant difference in therapeutic effect between sulphanilamide, sulphapyridine, and sulphathiazole. Though the protection given by these drugs in this experimental infection cannot be considered to be as spectacular as that obtained in the case of streptococcal or pneumococcal infections, the results are striking enough to justify a careful clinical trial with these drugs. The clinical data reported so far contain some favourable reports of treatment

with prontosil, sulphanilamide, and sulphapyridine in typhoid fever, persistent typhoid bacilluria and pyelitis, typhoid caries, etc., and also a few unfavourable ones; but these are too scanty to admit of a proper evaluation of the efficacy of these drugs in this infection (*cf.* Buttle, 1939; Kolmer, 1940). Very recently, good results are reported by Weilbaecher *et al.* (1940) in 3 of 4 patients treated with sulphathiazole. To obtain the best results, it is important that the treatment with these drugs should be instituted as early as possible and an adequate blood concentration of about 5 mg. per cent of the drugs maintained throughout the course of the infection.

Table II clearly shows sulphanilamide, sulphapyridine or sulphathiazole to be of no value in cholera. This negative result is of interest in evaluating the validity of some of the theories proposed regarding the mechanism of action of this class of drugs. Locke and Mellon (Mellon *et al.*, 1940) have advanced the anti-catalase theory which postulates that the therapeutic effect of the sulphanilamides is due to the injury caused to the organisms by hydrogen peroxide accumulated at the focus of infection as a result of the inactivation of the enzyme, catalase, by the drug. This theory requires that the organisms which produce catalase and are sensitive to injury by hydrogen peroxide should, as a class, be amenable to treatment by these sulphanilamides. But the case of *V. cholerae* apparently throws doubt on the validity of this theory for this microbe has been shown by M'Leod and Gordon (1923) to be markedly sensitive to hydrogen peroxide and also to produce catalase though to a small extent. Recently, Woods (1940) and Fildes (1940) have advanced the theory that the sulphanilamides act by inhibiting the action of an enzyme of some fundamental importance by competing with its substrate which is an 'essential metabolite' surmised to be *para*-aminobenzoic acid. According to this theory, the sensitiveness of a microbe to sulphanilamide would depend upon whether it could synthesize this substrate readily or not, i.e., a microbe that is not sensitive to the drug should be able to synthesize *para*-aminobenzoic acid in excess to overcome the inhibition by sulphanilamide. In the case of *V. cholerae*, we find a marked discrepancy between the *in vivo* and the *in vitro* results. As shown in table II, sulphathiazole shows absolutely no protective power against this micro-organism in mice. But *in vitro*, this drug possesses a striking bacteriostatic effect even in a dilution of 1 : 30,000 and this action is reversed by the addition of *para*-aminobenzoic acid, which by itself possesses no perceptible growth-stimulating effect on *V. cholerae*. This behaviour of the organism *in vitro* is not distinguishable from that of the streptococci or pneumococci, both of which respond to treatment with sulphathiazole. It is difficult to reconcile this difference in behaviour of sulphathiazole towards *V. cholerae* between

the *in vivo* and *in vitro* experiments, in the light of the theory of Woods and Fildes unless one assumes that this organism produces para-aminobenzoic acid in excess *in vivo*, while it is not able to do so *in vitro*. It is doubtful whether this is the case and further experiments are in progress to examine this question.

Till now, the action of the sulphanilamides have not been tested in experimental vaccinia virus infections but there are a few instances on record (McCammon, 1939; King and de Rozario, 1938) of the beneficial effects of prontosil and sulphanilamide in smallpox. The results recorded in table IV indicate that the drugs do not possess any specific therapeutic effect against this virus and obviously the above-mentioned favourable clinical results are due to the prevention of the secondary streptococcal infection of the lesions by these drugs. The sulphanilamide derivatives may thus be of use in smallpox, if at all, only in this direction.

The action of sulphanilamide and some of its derivatives in experimental rabies infections have previously been reported. Kirk (1939) has found 'prontosil' to have no effect on rabies of rabbits. McCrea (1939) has reported that sodium sulphanilyl-sulphanilate prevented the development of rabies in one-third of the number of rabbits; this result does not appear to be very definite. Gross, Cooper and Lewis (1939) have found only a very slight prolongation in life of rats infected with the virus when treated with sulphanilamide or sodium sulphanilyl-sulphanilate. Powell and Chen (*loc. cit.*) have declared sulphanilamide and sulphapyridine to be of no value in rabies in mice. Our results show that sulphapyridine and sulphathiazole also are of very little value in rabies of mice.

Summary

1. The therapeutic value of sulphathiazole in experimental *Bact. typhosum*, *V. cholerae* and fixed rabies virus infection in mice and vaccinia virus infection in rabbits has been investigated.

2. Experimental results show that the drug has appreciable therapeutic effect in experimental *Bact. typhosum* infection in mice and is of no therapeutic value in experimental *V. cholerae* and fixed rabies virus infection in mice and vaccinia virus infection in rabbits.

AGES OF EPIPHYSIAL UNION AT ELBOW AND WRIST JOINTS AMONGST 238 CHILDREN IN NORTH WEST FRONTIER PROVINCE

By L. K. LEDGER, O.B.E.

LIEUTENANT-COLONEL, I.M.S.

Civil Surgeon, Peshawar, N. W. F. P.

and

TEK CHAND WASSON, M.D. (Erlangen),
D.M.R. (Lond.)

Radiologist, Lady Reading Hospital, Peshawar,
N. W. F. P.

VERY frequently doctors are called upon to give an opinion as to the age of a person, either for medico-legal purposes, for entry to government service, or to enable a candidate to sit for university examinations, etc.

The registration of births is still extremely incomplete in India, even in municipal areas.

In January 1939, Colonel R. S. Townsend, gave us a copy of a paper written by himself and Rai Bahadur Dr. Raghunandan Lall, M.B., B.S., on age determination of Indian girls in the United Provinces by x-ray demonstration of epiphysial union.

His paper was published in the *Indian Medical Gazette*, October 1939.

The present paper is a continuation of his work. He obtained from the Provincial Government a grant of Rs. 200 for this purpose and this investigation owes its inception to his enthusiasm and interest.

The requisite number of boys and girls could not have been obtained without the support of Miss Littlewood, inspectress of girls' schools, N. W. F. P., and the hearty co-operation of the head-mistresses and head-masters of schools in Peshawar, to all of whom we acknowledge our debt of gratitude.

The first problem was to collect an adequate number of scholars whose ages could be proved to be between 13 and 20.

We appealed to all the schools in Peshawar and found that there were 788 boys and 200 girls on their registers whose official ages were recorded as between 15 and 19.

The school medical officers, Dr. Mohamad Shah, Dr. Shuaib, and Dr. (Miss) Mubarak Jan, carried out a long and conscientious investigation into the proof of age of all these children.

After consulting birth registers, municipal records, horoscopes, and so on, we were finally left with 189 boys and 49 girls whose ages were proved.

Out of nearly 1,000 scholars, only 238 could really prove their age.

The procedure was as follows :—

We decided to limit our investigation to the epiphyses around elbow and wrist joints for the following reasons :—

(a) To keep the cost within the available grant.

Very early we learnt that it was impossible to get an accurate antero-posterior view of the epiphyses at the upper end of the ulna as it was hidden by the lower end of the humerus and the x-ray was oblique to the epiphyseal line. In the following table therefore this epiphysis has been ignored.

We have considered union complete if (i) bony structure was continuous between diaphysis and epiphysis, or (ii) if the epiphyseal line was completely replaced by a thin line of dense bone. All films were examined with a strong convex lens to decide these points.

The scholars have been grouped into age groups as follows :—

13-14, 14-15, 15-16, 16-17, 17-18, 18-19, 19-20; boys and girls separately. The percentages of union of each epiphysis in each age group and either sex are shown in the following tables :—

Boys total 189

Age group	Number in group	RADIUS		Ulna, lower end	HUMERUS		Base, first metacarpal
		Upper	Lower		Lateral	Medial	
		ends			condyle		
		Per cent	Per cent	Per cent	Per cent	Per cent	Per cent
13-14	10	0	0	0	50	10	0
14-15	22	19	0	0	60	18	0
15-16	67	22	1½	6	80	25	3
16-17	48	33	4	6	98	42	12
17-18	24	86	25	40	100	90	53
18-19	8	88	40	62	100	88	62
19-20	10	100	40	50	100	100	90

<i>Girls total 49</i>							
Age group	Number in group	Per cent	Per cent	Per cent	Per cent	Per cent	Per cent
		Radius	Ulna, lower end	Humerus	Base, first metacarpal		
		Upper	Lower	Lateral	Medial	Condyle	Base
13-14	3	0	0	0	33	0	0
14-15	10	70	20	40	90	70	0
15-16	7	85	30	30	85	70	14
16-17	9	100	33	55	100	88	33
17-18	10	90	50	60	100	100	70
18-19	5	100	60	60	100	100	80
19-20	5	100	80	80	100	100	80

(b) To avoid difficulty which would have arisen if we had tried to undress the girls for x-ray of hip and knee. Even strictly purdah girls raised no objection to exhibiting an arm from under the burqa.

We used Agfa x-ray sensitive paper 15 inches \times 12 inches as cheaper than film, and not so much affected by the hot weather. Each sheet was large enough to radiograph the elbows and wrists of four subjects.

Six dozen papers sufficed for the 238 children.

The details of each child were entered on an index card which was numbered and the same number radiographed on to the sensitive paper. A specimen of the card used is in the protocol (p. 84). Great care was taken to centre the central ray in every case.

The numbers are of course too small for statistical treatment and the mathematical margin of error must be very high. But, as far as they go, they suggest that in more than 50 per cent of cases each epiphysis will be found united at the following ages for children in the North West Frontier Province.

The average age for European and American children has been taken from Shanks, Kerley and Twining's *Textbook of X-ray Diagnosis* where the findings of many authors have been collected.

Our findings support the view that epiphyseal union takes place earlier in India than in Europe.

In girls union appears to take place earlier than in boys; in some epiphyses as much as two years earlier.

In collecting data of our 238 children we took notes on the number of teeth and age at onset

Epiphysis	AGE OF UNION		Average age of union in European and American children of both sexes
	Boy	Girl	
Radius, upper ..	17-18	14-15	16-19
Radius, lower ..	Above 20	18-19	20
Ulna, lower ..	18-19	16-17	20
Humerus, lateral condyle	14-15	14-15	17-18
Humerus, medial condyle.	17-18	14-15	18
First metacarpal base ..	17-18	17-18	18-20

of menses. Our findings under these heads were as follows :—

appear to get their wisdom teeth later than boys, although their epiphyses unite earlier.

In the absence of x-ray the teeth are widely used to base the estimate of age, but the above tables suggest that the number of teeth present is a very unreliable evidence as to age.

Of the 49 girls included in our investigation 47 had started menstruation.

The ages at which these 47 girls started menstruation were :—

At age 11 years	2 per cent	{ By age 14, 54 per cent had menstruated.
12 "	6 "	
13 "	25 "	
14 "	21 "	
15 "	21 "	
16 "	17 "	
17 "	6 "	

These figures show that 46 per cent had not menstruated till after 14th year, as compared with Colonel Townsend's figure of 14 per cent

Boys

Age group	Number in group	Less than 28 teeth,		More than 28 teeth	Per cent
		Per cent	Per cent		
13-14	10	0	80	20	
14-15	22	8	87	5	
15-16	67	4	72	24	
16-17	48	3	79	18	
17-18	24	1	50	49	
18-19	8	14	62	24	
19-20	10	0	60	40	

Of 147 boys below age 17 years, 28 (19 per cent) only had more than 28 teeth.

Of 42 boys above 17 years, 18 (43 per cent) had more than 28 teeth.

Girls

Age group	Number in group	Less than 28 teeth,		More than 28 teeth	Per cent
		Per cent	Per cent		
13-14	3	33	66	0	
14-15	10	0	100	0	
15-16	7	15	85	0	
16-17	9	11	77	11	
17-18	10	10	60	30	
18-19	5	0	60	40	
19-20	5	0	60	40	

Of 29 girls below 17, only one (3 per cent) had more than 28 teeth.

Of 20 girls above 17, 7 (35 per cent) had more than 28 teeth.

The detailed number of teeth in each group was as follows :—

Boys

Age group	Teeth 27	28	29	30	31	32
13-14	0	8	1	0	0	1
14-15	2	19	1	0	0	0
15-16	2	48	7	5	2	3
16-17	2	38	3	2	0	3
17-18	0	12	2	4	5	1
18-19	1	5	0	1	0	1
19-20	0	6	0	1	3	0

Girls

Age group	Teeth 27	28	29	30	31	32
13-14	1	2	0	0	0	0
14-15	0	10	0	0	0	0
15-16	1	5	0	0	0	0
16-17	1	7	0	0	0	1
17-18	1	6	0	1	2	0
18-19	0	3	0	1	1	0
19-20	0	3	0	0	1	1

These tables regarding the eruption of teeth are interesting and show how very variable are the ages at which the teeth appear. The girls

and 25 per cent had still not menstruated at end of 15th year. Colonel Townsend's figure is 3 per cent.

Perhaps the later age of menstruation in the North West Frontier Province compared with the United Provinces is connected with the long cold weather here, more comparable to the European climate.

It is clear that an opinion as to the age of any adolescent cannot be given with great accuracy, even after consideration of the state of union of six epiphyses plus teeth plus date of menstruation. Any opinion must leave a margin of about six months older or younger than age given.

Before giving an opinion as to age in any medico-legal case we now complete the form shown in the protocol. This seems helpful in framing the opinion and also gives the support of facts and figures which is of assistance in maintaining the opinion given when opposed by counsel in court.

THE PRESENCE OF AN ENZOOTIC OF RICKETTSIAL INFECTION IN WILD RATS OF CALCUTTA

By R. K. GOYAL, M.B., D.Sc., Ph.D., M.R.C.P.,
M.R.C.S., F.R.S.E.

(From the School of Tropical Medicine, Calcutta)

COVELL (1936) drew attention to the existence of typhus infection in the wild rats of Simla Hills, and considered that these rodents acted as reservoirs of the infective agent for the spread of typhus fever. Cases of typical typhus fever are rare in Calcutta, but there is a possibility of the presence of mild and atypical cases which are not diagnosed correctly. Lepine and Bilfinger (1934) and Nicolle and Sparrow (1934) have described strains of typhus of feeble virulence. Typhus infection in wild rats, in the absence of any cases of the disease in human beings, has been reported. In view of these findings we determined the presence and nature of rickettsial infection in the local rodents.

A number of rats (*Rattus norvegicus*) caught in certain parts of Calcutta were examined as follows :—

The rats were killed by drowning and the brains were removed with sterile precautions and a saline suspension of the brain was injected intra-peritoneally into one or more male guinea-pigs. In a number of experiments, a variable number of the inoculated guinea-pigs died within 24 hours. Although the brains were removed with great care, still a number of organisms

were found to be present; they will be referred to later. In view of the presence of the secondary bacterial infection in certain rats, the technique was modified. The brains were kept in the refrigerator and the bacterial purity was controlled by broth culture; only bacteria-free brains were used for guinea-pig inoculation. The temperature of the guinea-pigs was recorded every morning and those showing definitely a febrile reaction on more than one day were sacrificed and their viscera examined. Covell (*loc. cit.*) found that the rise of temperature was generally up to 103°F., rarely exceeding 104°F., after the infection, and during the first four passages it was unusual for the pyrexia to persist for more than 3 or 4 days, but in later passages it continued for 10 to 12 days on several occasions. We had different experience in Calcutta. The stock guinea-pigs had a temperature range of 102°F. to 103.6°F., the temperature occasionally rose to 104.2°F. and very rarely reached 105°F. The thermometer was pushed up to two inches from the anal aperture to get this temperature. The temperature was lower by 0.5°F. to 1°F. when the mercury bulb was just introduced into the anal canal. These figures relate to the temperature taken in summer months between 10 a.m. and 10-30 a.m.; there was a rise of temperature of about 0.5°F. by 11-30 a.m. The range of temperature was lower in winter months, i.e., 100.4°F. to 102.4°F., occasionally going up to 103°F.

One hundred and one rats caught in certain areas of Calcutta were examined; the results were as follows :—

The guinea-pigs showing a mild febrile reaction and slight thickening and congestion of the tunica vaginalis after an incubation period of 4 to 21 days were considered to be positive. The rise of temperature was from 1°F. to 3.6°F., fever lasted generally from 3 to 4 days, but was present irregularly in some cases up to at least three weeks. Smears taken from the tunica vaginalis, spleen, and brain, and stained with dilute Giemsa's stain for 18 hours at 37°C., showed the presence of rickettsial bodies both intra-cellular and extra-cellular. They were pleomorphic, varying from minute coccoid forms to moderately long bacillary forms. The infection was passed from one guinea-pig to another but tended to become attenuated. Bacteria-free suspensions of tunica vaginalis inoculated on the chorio-allantoic membranes

of growing chick-embryos produced well-defined whitish patches in 2 to 4 days. A suspension of the infected membranes definitely reproduced the disease in male guinea-pigs.

Congestion and patchy necrosis of the scrotum were observed only in one case, but the inoculation of the suspension of the tunica vaginalis failed to reproduce the scrotal reaction; the tunica vaginalis was found to be thickened and congested.

Having demonstrated the presence of a rickettsial infection in the wild rats of Calcutta, the Weil-Felix reaction of the serum of infected guinea-pigs was investigated. Blood was drawn before the animals were infected and in various stages of infection. A certain number of other normal guinea-pigs were tested at the same time as controls.

The final dilutions of the serum put up were : 1/25, 1/50, 1/100, 1/200 and so on. The proteus strains used were HX19, HXK and HX2, and the O suspensions prepared therefrom were used. The results are as follows :—

1/25 with OX19 and OX2, there was no rise of agglutinins after more injections. These findings suggested either that the local rickettsial strain had no relationship to any of the three strains of the proteus group or that a fourth strain was at work. In view of the absence of reported cases of clinical typhus fever in Calcutta, we examined the sera of 100 cases of obscure fevers for proteus agglutinins; none of the sera agglutinated the OXK, OX19 and OX2 suspensions in high dilutions. It could be concluded that the rat strain was probably non-pathogenic to man. An emulsion of spleen and tunica vaginalis from two febrile guinea-pigs was injected subcutaneously into a volunteer; no untoward symptoms developed over a period of three months. A second volunteer injected with similar material remained well for a week, but could not be traced later. It can be inferred from all the data available that the rat strain is probably non-pathogenic to man.

Our attention was next directed to the presence of rickettsiae pathogenic to guinea-pigs and

Weil-Felix reaction performed with the sera of normal and infected guinea-pigs

				2	1/50	1/100	0
41	31

Thirty-one guinea-pigs were tested for the presence of proteus agglutinins when the temperature was coming down or in late convalescence. There was no appreciable rise of agglutinins as compared with 41 normal guinea-pigs. The highest titre was 1/50 with OX19, 1/100 with OXK and 1/50 with OX2. As there is no rise in proteus agglutinins in guinea-pigs infected with the louse-borne typhus, much significance cannot be attached to this observation.

It was essential to immunize some other animals to demonstrate the proteus relationship of the rickettsial bodies. Six rabbits were given intra-peritoneal injections of suspensions of rat brains in gradually increasing doses of 1 to 10 c.c.m. The highest titre obtained after a few injections was 1/50 with OXK suspension and

monkeys in the bodies of ticks. A large number of specimens of *R. sanguineus* and *A. persicus* were collected for us by Drs. D. N. Roy and B. C. Basu. About a dozen were examined each time; they were ground up in sterile saline and treated with ether for at least four hours to diminish appreciably the number of bacteria present. An intra-peritoneal inoculation into guinea-pigs and an intradermal injection into monkeys failed to produce any untoward symptoms. The same technique was employed in the examination of bed-bugs, lice, and fleas with negative results in each case.

The local rat strain was next compared with a definitely pathogenic rickettsial strain. For this purpose the XK strain from Kasauli was obtained through the courtesy of Dr. R. O. A.

Smith. It produced marked peritoneal effusion and enlargement of spleen in inoculated guinea-pigs, unlike the reactions produced by the local strain. In a preliminary series of experiments there was some evidence that the local strain was antigenically different from the Kasauli strain.

Lepine and Bilfinger (*loc. cit.*) reported that, although they obtained the rickettsial strain from a large percentage of rats at one season of the year, only two strains were isolated from 475 brains at a later date. We were able to isolate rickettsiae from most of the wild rats from June 1937 to December 1938. But we have failed to get any positive results from September 1939 to July 1940, although 335 rats dead for a few hours have been examined. All the inoculated guinea-pigs in the second series of experiments were receiving a diet of bran and gram which is deficient in vitamins; still we did not get any febrile reaction. It is clear that we were previously dealing with an enzootic of typhus fever in the wild rats of Kidderpore area which later died out.

The organisms isolated from the 335 rats were studied with a view to finding the nature of concomitant organisms in the brains of wild rats. The following organisms were isolated from the brains examined :—

<i>B. proteus</i>	..	10 cases.
Coliform bacilli	..	49 "
<i>B. pyocyanus</i>	..	62 "
<i>Strep. viridans</i>	..	23 "
<i>Micrococcus catarrhalis</i>	..	2 "

None of the *proteus* strains isolated agglutinated with any of the OX19, OXK, or OX2 suspensions. Out of the 49 coli form strains, 22 fermented lactose with the production of acid and gas, the other 27 strains were non-lactose fermenters giving mostly atypical sugar reactions. None of the strains was agglutinated by a mixed salmonella serum and a majority of them tested with the Shiga serum gave negative results. Three strains gave the biochemical reactions of *B. metadyserteriae* C, *B. ceylonensis* B, and *S. paradysenteriae* (Flexner).

Summary

An enzootic of typhus fever has been described in wild rats of Calcutta; this rat strain was most probably non-pathogenic to man.

THE EFFECT OF STOCKING RICE FIELDS WITH SULLAGE AT KHURDA ROAD ON ANOPHELINE BREEDING*

By V. VENKAT RAO, M.R.S.A.N.I. (Lond.)
Senior Malaria Inspector, B. N. Railway

WHILE writing a report on 'The present use of naturalistic measures in the control of malaria', Hackett, Russell, Scharff and Senior White (1938) found that there was a difference of opinion among themselves as to the effect of rotting stubble in water in rice fields after reaping. Therefore, Senior White asked all the malaria inspectors working under him, including the present writer, to select a typical field, to rot stubble in it as soon as possible after the harvest, and to study the effects in the subsequent rice-growing season in comparison with another typical field not so treated.

The value of naturalistic methods in rice fields cannot be over-estimated. There are several areas in this country where rice fields breed the local vectors in large numbers. Rice fields situated along foot-hills and tapping seepages have been shown to breed *Anopheles fluviatilis*, *A. minimus* and *A. varuna*, in the Jeypore hills (Mandal, 1938). Venkat Rao (1938) has shown that *A. annularis*, the main vector in the Orissa coastal plains, breeds in significant numbers in all rice fields at Khurda Road. On account of their extent, they are costly to deal with. They cannot be effectively drained away in those large areas 'where the flooding of rice is entirely dependent on an intermittent seasonal rainfall' (Hackett *et al.*, 1938). Therefore, any anti-larval measures which do away with chemical larvicides and which do not interfere with the irrigation of the fields are to be welcomed.

The present writer has made the study suggested, at Khurda Road in Orissa where, owing to the practical elimination of other types of breeding places, rice fields constitute almost the sole breeding place of the local vectors. He, however, observed that, after harvest, practically no stubble was left in the fields and that the little that remained would not, even after rotting, show any substantial difference in the fauna. He, therefore, decided instead to stock the fields with crude sullage, as another form of rotting, throughout the dry season and to study the effects in the next rice-growing season.

The ryots at Khurda Road did not offer obstruction to this method. They even welcomed it as it would enable them to plough the fields easily in the dry season, when, otherwise, the ground would be too hard for ploughing.

The sullage from the railway colony at Khurda Road station was utilized for this purpose. The main outfall drain empties itself into a *kutcha*

* A summary of this paper was read by the writer before the Fifth Annual Conference of the B. N. Railway Malaria Inspectors held at Dongargarh (Central Provinces) in March 1940.

† Proof of this will be furnished by Senior White and Adhikari in a paper still under preparation.

drain, which passes through a large number of rice fields and is finally led into the Daya river, one of the branches of the Mahanadi. During the season favourable to the breeding of *C. fatigans* (December to March) this drain is regularly cleaned and oiled by the sanitary staff of the railway in order to prevent mosquito nuisance and the spread of filariasis. This does not, however, prevent the ryots from diverting the sullage into their fields during the dry season to facilitate ploughing. When they take the sullage, they do not take the small quantity sufficient for wetting the soil but try to allow as much sullage as possible to run into the fields and thus convert each field into a sullage swamp, breeding *C. fatigans* in large numbers. Oiling such swamps is both costly and inefficient.

One field situated close to the main sullage outfall drain was selected for the experiment and another field in the same area, which was of nearly the same size, was selected as 'control'. Sullage from the main drain was let into the experimental field on one day each week. As soon as a depth of half an inch was obtained, the sullage flow was cut off and diverted again into its normal course. Usually, in the dry months (March to June) when this experiment was done, the field became dry in 24 to 36 hours. There was, therefore, no danger of the field being converted into a sullage swamp, breeding *C. fatigans* heavily. The field was ploughed when dry by the ryot about once in a month in this period.

At the beginning of the rains, the ryot sowed rice seeds in the field. In this part of Orissa, the rice is 'broadcast' in the fields and not 'transplanted'. The field was never dried till harvesting and the depth of water in it varied from one inch to three inches. The field was irrigated with rain water only, there being no seepages in it. The 'control' field also satisfied the same conditions, except that no sullage was allowed to run into it at any time during the previous dry season.

Larval sampling was made in both the fields from 1st July, 1939 to 31st December, 1939, by the same man throughout. The sampling was made by making a total of 25 ladle dips in each field once a week. The dips were made mostly at the edges but a few were made also as far inside the field as the ryot would allow us to proceed while the rice was growing. Neither this nor larval estimation by dipping are claimed to be satisfactory methods but they were adopted for want of better methods.

The larvæ collected each month from the experimental field (which was 'treated' with sullage as described above) are shown in table I.

The larvæ collected from the 'control' field (which was not 'treated' with sullage) are shown in table II.

Discussion

The first four species are definitely not carriers. There is evidence to show that

December ..	20	19	17	43	4	4	28	3
TOTAL	21	117	175	83	27	139	70

A. culicifacies is not a carrier in this area (Senior White, 1936 and 1937). *A. annularis* is proved to be a carrier at Khurda Road (Sarathy, 1932), while *A. aconitus* was found infective at Dhanmandal and Malatipatpur, two endemic stations, 100 miles north and 22 miles south of Khurda Road, respectively. *A. varuna* has so far been found to be a carrier in Jeypore hills (Senior White, 1936 and 1937), in the Central Provinces (Senior White, MSS.), in Chota Nagpur (Senior White and Das, 1938) and in Bengal (Iyengar, 1934, and Roy, 1938).

The above tables show that, in the 'treated' field, there is a marked increase of non-carriers (this does not, however, apply to *A. barbirostris* and *A. hyrcanus* which appear to prefer clean waters) and a very substantial reduction in carriers, while the 'untreated' field breeds both the carriers and non-carriers freely.

This experiment also shows that (1) allowing sullage into the rice fields might be a satisfactory method of sullage disposal in rural areas, where no other method is available or practicable; (2) *C. fatigans* can be controlled without the use of oil; and (3) filariasis, which is widely prevalent in this area, can be checked. Whether the addition of sullage to the field, which is not otherwise well manured, has also the effect of improving the crop could not, of course, be studied by the writer.

It might be said that this experiment was carried out in an area adjacent to a railway colony which represents urban, and not rural, conditions. The writer admits the force of this argument. He would, however, like to point out that Khurda Road station has a population of about 3,500 only and is situated in typical rural surroundings. In villages having about the same population, sullage accumulates near houses or is allowed to run to waste and, in any case, it is not only not disposed of in a proper manner but is allowed to become a positive nuisance. The method advocated in this paper would be found applicable to such cases.

The writer is aware that this experiment carried out in one field, and in one season, cannot prove anything conclusively and can at best indicate the possibilities of this form of naturalistic measures. In order to obtain more comparable results and to see if, by this treatment, the crop can be improved, a further experiment on a much larger scale is proposed to be carried out at the same station in 1941 by the writer with the co-operation of Mr. P. D. Dixit, M.Sc., paddy specialist, Orissa, Dr. R. G. Panigrahi, M.B.B.S., D.P.H., malaria officer, Orissa, and Mr. V. Ramakrishna, B.Sc., assistant malaria inspector, B. N. Railway.

Summary

(a) Allowing sullage into rice fields in the dry season once a week without converting the fields into sullage swamps has the effect of increasing the breeding of non-carrier anopheles and greatly decreasing the breeding of carriers, besides indicating a method whereby *C. fatigans*, and with it filariasis, can be controlled.

(b) Whether the same procedure has the effect of improving the crop is not yet ascertained.

Acknowledgment

The writer is grateful to Dr. R. Senior White, F.R.S.E., Malariaologist, B. N. Railway, for the guidance and encouragement he gave throughout the period of investigation.

A SIMPLE METHOD OF OBTAINING ANÆROBIOSIS

By C. L. PASRICHA
MAJOR, I.M.S.

Professor of Bacteriology and Pathology
and

S. K. GHOSH

(From the Bacteriology Department, School of Tropical Medicine, Calcutta)

THE well-known principle of removal of oxygen during the rusting of iron is utilized for producing anaerobiosis. Any container capable of being hermetically sealed can be used, one of the usual desiccators with a stopcock or an improvised apparatus such as a screw-cap fruit jar or an ordinary glass tumbler covered with a glass plate (a petri-dish cover serves the purpose well), and made air tight with plasticine or other suitable plastic material, gives entirely satisfactory results. Some moistened iron filings are placed at the bottom of the jar, one of the usual oxygen indicators (for example, alkaline-glucose-methylene-blue mixture) placed along with the cultures, and the jar sealed. After 6 to 12 hours, according to the size of the jar and the amount and quality of iron filings, the colour of the indicator is discharged and complete anaerobiosis obtained. Approximately 60 grammes of iron filings are sufficient to produce complete anaerobiosis overnight in a container of about 1,000 c.cm. capacity. Smaller amounts of iron filings take longer time.

This method of producing anaerobiosis is efficient. Cultures of strict anaerobes both in liquid media and on surface agar can be easily obtained. Compared with parallel inoculations incubated in McIntosh and Fildes' jar, employing the standard technique of producing anaerobiosis, there is no appreciable difference in cultures made in liquid medium, but there is a difference in the amount of growth on solid medium. This difference is however of not any practical importance. The test organisms used were *Clostridium tetani*, *Cl. histolyticum* and *Cl. botulinum*. When comparatively clean iron filings are used there is no detectable amount of hydrogen sulphide produced (using lead acetate papers as indicators).

There is, as will be readily appreciated, a reduction in the tension inside the jar. This can be readily demonstrated by opening the jar with the opening immersed in water when water to about 1/5th the volume of the jar will flow in. This reduction in pressure has certain advantages in that, provided the seal is efficient, the atmospheric pressure will tend to keep the jar well sealed. If however it is desired to equalize the pressure, then a neutral gas (such as nitrogen, hydrogen, or CO₂) can be admitted after anaerobiosis has been obtained. Where facilities are available the jar can be evacuated and hydrogen admitted, but comparative tests

with this method and without any preliminary evacuation have shown no real advantage. The resulting growth is approximately the same.

Another very great advantage of this method of producing anaerobiosis is that the jar can be opened as often as desired to examine the cultures, and closed again. The partially-oxidized iron filings appear to be more active than new filings.

Many other uses of iron filings for producing anaerobiosis will suggest themselves. Some of the methods tried and found to give satisfactory results are:—

(1) Sterile iron filings in a flat screw-capped bottle can be used to produce anaerobiosis to allow the growth of strict anaerobes on surface agar in that bottle. Liquid cultures can be obtained if the iron filings are contained in an enclosed small test-tube.

(2) Used at the bottom of an agar deep, the resulting anaerobic condition is more satisfactory than with the usual glucose agar.

(3) Used at the bottom of a broth tube in place of cooked meat in cooked-meat broth.

(4) Used on top of a pushed-in cotton-wool plug and the test-tube then sealed with a rubber cap. Complete anaerobiosis is obtained in a few hours.

Summary

An anaerobic method is described based on the well-known principle of oxidation of iron filings. The method is simple and efficient. No expensive and complicated equipment is required. There is no need for a hydrogen cylinder or a generator for hydrogen, vacuum pump, or for any one of the devices of palladized asbestos wool. In the trials carried out this method has given satisfactory results.

A Mirror of Hospital Practice

A CASE OF PLAGUE SUCCESSFULLY TREATED WITH SULPHAPYRIDINE

By Sir R. N. CHOPRA, Kt., C.I.E., M.A., M.B.,
S.C.B. (Cantab.), F.R.C.P. (Lond.)
BREVET-COLONEL, I.M.S. (Retd.)

A. J. H. DEMONTE, D.P.BACT., I.M.D.
and

B. C. CHATTERJI, M.B., D.T.M.

(From the School of Tropical Medicine, Calcutta)

CASES of plague are admitted from time to time to the Campbell Medical School and Hospital. Two such cases were admitted during 1939, and were under the care of one of us (B. C. C.). No anti-plague serum was available so that treatment by other agents had to be resorted to. The first case, admitted early in the year, was treated with iodine intravenously, and died on the third day of her stay in hospital. The second case, which forms the subject of this report, was that of a female child aged 6 years who was admitted with symptoms of bubonic plague on 6th December, 1939. The child and her mother had left their home to arrive in Calcutta four days previously because plague had broken out in their village and one of their neighbours had died of it. The child developed fever and a bubo a day before admission to hospital.

The success that has attended the use of sulphapyridine in the treatment of several bacterial infections and the difficulty of getting anti-plague serum led us to employ this compound for the treatment of this case from which *Pasteurella pestis* was isolated from material obtained by puncture of the bubo.

The patient was given one tablet (0.5 gm.) sulphapyridine every four hours on the first night. The

following morning, her condition appeared to be worse; she was very toxic and delirious, her temperature was 103°F., pulse 120, respiration 28, and both her lungs were congested. Prognosis was bad and it was decided to push sulphapyridine therapy even to toxic limits. Accordingly one tablet of sulphapyridine was administered orally every four hours, night and day, and in addition 1 gramme of the soluble sodium derivative of sulphapyridine was administered intramuscularly once every day. This was done for three days. The lung condition had progressed through the stages of congestion to consolidation and broncho-pneumonia of both the lungs was present. On the 10th and 11th December, sulphapyridine (soluble) was not available, but the oral administration of tablets was continued as previously. On 12th December, the soluble compound being again available, 1 gramme was administered as before in addition to the tablets. The temperature fell to normal on 13th December and further injection of M&B. 693 (soluble) was stopped, as the child's condition had improved considerably, but the oral administration of the tablets was continued in the same dosage for two more days, when, on the 15th, it was reduced to one tablet twice daily, and was finally discontinued on the 17th. The temperature had remained normal since the 13th. The bubo which had softened broke down on 10th December, but resolution was very slow and the patient was discharged on the 26th of January 1940. She had therefore received 31.5 gm. of sulphapyridine of which 29.5 gm. had been administered during the first eight days of her stay in hospital. No signs of intolerance were exhibited, in spite of the fact that a maximum dosage of 3 to 4 gm. (6 tablets orally and 1 gm. intramuscularly) had been administered daily for eight days to an ill-nourished child of six years.

Pasteurella pestis was isolated from material obtained by puncture of the bubo made just before sulphapyridine therapy had commenced and again 12 hours later, after 1.5 gm. M&B. 693 had been administered orally. No organisms were isolated from subsequent samples collected after 14 and 20 grammes of the drug had been given. The blood was not examined before the commencement of treatment but no organisms were isolated from the sample collected on the 6th after 3½ gm. had been given orally and 1 gm. intramuscularly, in spite of inoculation into two white rats. The organisms from the bubo were found to be virulent to white rats and guinea-pigs.

Carman (1938) records a lowering in the mortality rate by 50 per cent among six cases of oriental plague treated by him with prontosil soluble where previously his results for 9 similar infections were 100 per cent mortality. This case is therefore published, not as a proof that sulphapyridine is efficacious in the treatment of plague, but as an instance of its value when little else was available for the treatment of that disease.

We are grateful to Col. Mallya, the superintendent of Campbell Medical School and Hospital, for allowing us to publish this case.

PSEUDO-PANCREATIC CYST IN A MALARIAL SUBJECT

By M. G. KINI, M.C., M.B., M.Ch. (Orth.), F.R.C.S. (Edin.)
Surgeon, King George Hospital and Professor of Operative Surgery, Andhra Medical College, Vizagapatam (S. India)

THE aetiology of pseudo-pancreatic cyst is generally attributed to an injury of the upper abdomen or a previous attack of acute necrosis of the pancreas causing an effusion in the lesser sac. The effusion may be of various types, it may be clear watery or gelatinous or straw coloured and may contain some extravasated blood. In a few cases it may be coloured green due to the presence of bile. The size of the cyst varies, it may be small or very large, it may be single or bilocular or multi-locular. The diagnosis that the cyst has a pancreatic connection is usually made by the presence of ferments of the pancreas. The presence of the three ferments, especially trypsin, points to its direct connection with the pancreas or that it is a cyst arising from the pancreas. The presence of a starch splitting enzyme alone is not a sufficient proof that it is a pancreatic cyst as this is found in other types of abdominal cysts or even in cases of ascitic fluid. The following case is interesting because there was a big bilocular cyst in the lesser sac, the mid-colic vessels dividing it into two loculi. It was not due to an injury but started with attacks of malaria.

A Hindu male boy, aged 17 years, was admitted on the 6th June, 1938, with a history of acute shooting pain of two months' duration in the left hypochondrium. The pain usually started with the taking of food and continued after food. He noticed a swelling which was firm and was situated more in the left hypochondrium and left side of the epigastrium. On admission he was found to be well nourished, not jaundiced and slightly anaemic, the spleen being palpable two fingers below the costal margin. On examination, the tumour was found in the left hypochondriac region which moved slightly with respiration with no pulsation or dilatation of the veins in front of the tumour. It was globular in shape, dull on percussion and slightly tender. A gap could be felt between the spleen and the tumour and slight thrill on coughing. His urine was found to be normal, motion contained no ova or fat cells, and his urine diastase was found within normal limits. His blood

pressure was 100/60 and his circulatory system was normal. His blood contained gametocytes of malignant tertian malaria. He was treated for malaria and later given aolan injections for the enlargement of the spleen, which reduced its size to a considerable extent. Barium meal radiographic examination showed a bilocular swelling pressing the greater curvature of the stomach and causing two separate dents on it (see figure).

Stomach after barium meal with two dents on the greater curvature due to pressure by the bilocular cyst.

He was operated on on the 16th by a left paramedian incision. A big cyst arising from the lesser sac pressing against the enlarged spleen was found. The mid-colic vessels were found dilated and stretched over the cyst causing loculation. It was difficult to remove the cyst and so it was marsupialized with a Malecot's catheter *in situ* and the abdomen closed in layers. Constant suction drainage was established for three days. Intermittent drainage every three hours was started subsequently still retaining the Malecot's catheter. At the end of eight days, it was removed and the discharge was found to be small in quantity and the sinus healed in about 20 days.

The fluid from the cyst was straw coloured with a sheen on the surface. It was alkaline in reaction containing a trace of chlorides. The deposit showed red cells and leucocytes, but no crystals. Of the enzymes found, amylase was in good quantity, lipase a trace and proteolytic ones nil. Urea content was 47 mg. per 100 c.c.m. fluid..

He was discharged but six months later he was readmitted for pain with enlargement of the spleen. He had attacks of malaria and malarial parasites were found in large numbers in his blood. He was treated for a time for malaria and as the pain did not subside, he was operated upon again. At the second operation it was found that the cyst had entirely disappeared, the spleen was found very much enlarged and there were no adhesions though many were expected as a result of previous operation. The abdomen was closed in layers and the patient was discharged cured.

He was admitted for a third time four months later for pain. His spleen was found enlarged and he gave a history of recurrent attacks of malaria. A barium meal examination was done and it was found that the stomach was normal and showed good emptying though the intestines showed here and there evidence of slight

obstruction. He had regular motions and so it was thought not advisable to open his abdomen, and he was treated for his malaria.

He comes of a hysterical family, his mother is suffering from hysteria. On investigation, his recurrent attacks of colic were found to become severe every time the father asked the boy to return to school. Once his doctor gave him morphia for the attack of pain and since then the attacks became very frequent and the boy demanded morphia to be given. His general condition has improved. He reports in his letter dated 3rd September, 1940, that he is keeping good health except for vomiting of bile once a fortnight. He states his spleen has gone down in size and the report from his doctor shows he is now free from malaria. A change of place has done him good.

Points of interest

(1) A bilocular cyst in the region of the pancreas is described associated with enlargement of the spleen and attacks of malaria. After marsupialization the cyst had completely disappeared.

(2) Recurrent attacks of colic were complained of, and each time blood examination showed the presence of malignant tertian malarial parasites. He had an enlarged spleen to start with, which got smaller after treatment by injections of aolan, and subsequent attacks of malaria increased the size of the spleen. Though the cyst was not connected with the spleen, it is difficult to say whether malaria had not something to do with the development of the pseudo-pancreatic cyst and hence it is reported.

(3) The cyst contained a starch-splitting enzyme with a trace of lipase and there was absence of proteolytic enzymes. It cannot be classified as a true pancreatic cyst. Being in the region of the lesser sac, it is classified as a pseudo-pancreatic cyst. Is it possible, due to recurrent attacks of malaria, the perisplenitis caused effusion in the lesser sac? It is well known that in cases of enlarged spleen in malaria the splenic artery undergoes endarteritis with thickening of the wall. The splenic artery supplies branches to the pancreas also. Due to the changes in the blood vessels does the pancreas share in the chronic inflammation and does it reflexly produce an effusion in the lesser sac? So far no cases of this type have been published, neither has the clinical condition of this case shown any evidence of pancreatic disturbance.

(4) Latterly, the boy had become hysterical. The severity of the colics was found to synchronize with the father's asking the boy to go to school. Having once got morphia the boy began to get frequent attacks of colic demanding the same injection. Now he is free from colics and malaria but complains of vomiting of bile once a fortnight. He reports his spleen has gone down in size. He has been asked to return for further investigation.

(5) The bilocular nature of the cyst causing dents upon the greater curvature of the stomach, as shown in the radiographic picture, is due to enlargement of the spleen which prevented the

expansion of the sac towards the left hypochondrium and lumbar region thus exerting pressure on the stomach.

My thanks are due to the Radiologist, Dr. P. Kesavaswamy, for the photograph and to Dr. V. K. Narayana Menon, Professor of Biochemistry, for his report on the biochemical nature of fluid sent to him for examination.

TREATMENT OF GONORRHOEA WITH M.&B. 693 : 75 PATIENTS

By C. E. R. NORMAN

Chief Medical Officer

and

D. DAVID

Assistant Surgeon, South Indian Railway Company, Limited, Golden Rock

THE urethral smear was positive in every case before treatment. Treatment consisted of 4 days' oral administration of M.&B. 693, two tablets three times a day, one day's interval and another course of 4 days' treatment. No rashes were observed; a certain number of cases complained of headache and giddiness, a few

Number of cases	Duration	URINE SEDIMENTS AFTER TREATMENT		Unfinished
		Positive	Negative	
10	1 to 5 days	2	8	Nil
11	1 week	2	9	Nil

vomited occasionally in two cases of which treatment was suspended for a day, and about half a dozen cases showed a sudden rise of temperature at the end of treatment.

HYDATID CYST IN THE TRANSVERSE MESOCOLON

By MANMOHAN NATH KHANNA, F.R.C.S. (Eng.), F.R.C.S. (Edin.)
Honorary Surgeon, Sir Gangaram Hospital, and Ishardas Kapur Hospital, Lahore

History.—A boy, ten years old, was referred to me for a visible growth in the upper part of the abdomen, weakness, jaundice, dyspepsia and constipation. The swelling was first noticed over four years ago, and later it went on increasing gradually until it attained the present dimensions. He had become much emaciated and had many attacks of jaundice, during which his stools were clay-coloured and the urine was very high coloured, pointing to obstruction of some sort to the free passage of bile.

Examination.—Emaciated child with marked jaundice. A lump visible in the upper part of the abdomen in the mid-line, the size of a tennis ball, firm in consistency, moving with respiration, not connected with the liver. Chest barrel-shaped as a result of the upward pressure of the lump. Provisional diagnosis of a retro-peritoneal growth or a hydatid cyst was made, in spite of the absence of any history of his association with dogs. Blood count showed 5 per cent of eosinophils. No other test for hydatid disease could be carried out for want of facilities. Operation was advised and the child was admitted into Ishardas Kapur Hospital, Lahore, on 1st July, 1940.

Treatment.—On 2nd July under general anaesthesia the abdomen was opened by a right para-median incision. General survey of the abdomen was rapidly made. Gall-bladder was full, tense and shining, could be emptied by gentle pressure, and no stones could be felt. Liver free and surface smooth; spleen normal, appendix normal, stomach and intestines free. Omentum and transverse colon free, but on lifting the transverse colon up, a large growth was seen and felt in its mesocolon. The growth was found to be about 11 to 12 inches in diameter, extending down to the vertebral column, but there was no pedicle; hence its entire removal was not possible. The swelling was firm but not hard. The great omentum and the transverse colon were lifted upwards and the small intestines pushed downwards. The lower part of the transverse mesocolon was exposed, and a bloodless spot was chosen. Incision was made in the peritoneum and the growth exposed. Trocar and cannula were pushed in and fluid came out under tension, it contained sand-like granules. Diagnosis of hydatid disease was made and the opening was enlarged. The whole of the true cyst was removed by forceps in one piece. This cyst-wall was found to be smooth on the outer side, which was in contact with the adventitious cyst formed from the mesocolon; and was rough and granular on the inner side and contained a number of small cystic projections arising from it. There was no haemorrhage from the cavity. The cavity was thoroughly cleaned with ether and swabs of gauze, and was then closed. The stump was invaginated and the peritoneum stitched over it. Abdomen was closed.

The fluid which was collected at the time of tapping was examined by the hospital pathologist, who reported the presence of hooklets. Thus the diagnosis of hydatid was confirmed.

The boy regained consciousness after two hours and was given glucose saline per rectum and intravenously. Next morning, distension of the abdomen, which showed signs of increasing, was noticed. He was, at once, put on 1/12th of a grain of morphia every six hours, heat to the abdomen, flatus tube, etc. The condition disappeared on the fourth day. From that day, he began to show signs of improvement, the jaundice began to decrease, the urine became lighter in colour, and bile began to appear in the stools. He made a complete recovery in two weeks.

When discharged from the hospital, he was quite well, with good appetite and no discomfort of any sort, no lump in the abdomen and no jaundice. But the lower part of the chest which had become widened out still remained in that state, and it is presumed it will take a long time to return to normal. The cyst was pressing upon the bile passages causing jaundice, upon the stomach and intestines causing dyspepsia and constipation, and pushing the chest wall out in order to make room for itself.

In conclusion, my sincere thanks are due to Dr. Balbir Singh, the hospital pathologist, for examining the fluid, and finding the hooklets for me, and to the medical superintendent of Ishardas Kapur Hospital, Lahore, for allowing me to report this case.

Summary.—A case of hydatid cyst in the transverse mesocolon has been described.

A CASE OF SNAKE BITE SUCCESSFULLY TREATED WITH THE HELP OF THE 'IRON LUNG'

By R. LINTON
MAJOR, I.M.S.

Superintendent, Mitford Hospital, Dacca
and

NASIMUDDIN SARKAR
Teacher of Medical Jurisprudence, Dacca Medical School

ON the 12th July, 1940, a boy aged about 12 years, was admitted into the Mitford Hospital, Dacca, for the treatment of snake bite.

The history of the case was as follows: The boy was sleeping on the floor of a *katcha* house about four miles away from Dacca town. At about 3-30 a.m. he suddenly cried out that something had bitten him on the right foot. On examining the foot it was found that there were two small punctured wounds with two drops of blood on the inner side of the right foot. A dead frog in a macerated condition was found on the patient's bed. The boy's relatives at once called an *ojha* to treat the case. He continued treatment up to 6 a.m. when the boy became unconscious, and it was decided to bring him to the Mitford Hospital where he arrived at 9-30 a.m.

Condition on admission.—The patient was deeply unconscious and his reflexes including the corneal reflex were abolished. The pulse was rapid, regular and fairly full. Respiration was shallow, irregular and infrequent, the rate being six per minute. The patient was deeply cyanosed and there was fine froth at the corners of his mouth and nostrils. There were two small punctured wounds about one inch apart on the instep of the right foot, and the foot and ankle were considerably swollen and oedematous. There was no discharge from the punctures and no ecchymosis. The case was diagnosed as a bite by a poisonous snake of the colubrine group.

Treatment.—An injection of 20 c.c.m. of antivenene was administered at once by the intravenous route and respiratory and cardiac stimulants were also given. In spite of this the condition of the patient became worse. At this stage the senior author saw the case and suggested that the patient should be put in the 'iron lung', which had recently arrived as a free gift from Lord Nuffield. It was got ready and the patient was put in at 10-15 a.m. By this time the case was regarded as hopeless as his respiration had practically ceased and the pulse was imperceptible at the wrist. The respiration rate was adjusted to 18 per minute and the first effect noticed was the blowing out of a quantity of fine froth which was wiped away by an attendant. At 10-30 a.m. the cyanosis disappeared and at 10-45 the pulse became strong and full. The administration of antivenene was continued in the meantime through the arm hole in the 'lung' and an amount of 110 c.c.m. in all was given. At about 11-15 the corneal reflex was restored and the patient responded to questions at 11-30. Thereafter improvement was rapid but the patient was kept in the 'lung' until 3-15 p.m. when he was taken out and given some food. He had a febrile reaction for the next 24 hours after which his convalescence was rapid and uneventful, and he was discharged from hospital on the 20th when the condition of his foot had cleared up.

Discussion.—It is not claimed that the 'iron lung' is a miraculous cure for snake bite. In fact it would probably be of no use at all in bites by the viperine group of snakes, or in colubrine cases where a very large dose of venom had been injected. In a case of colubrine snake bite, death is due to respiratory failure

but the artificial respiration produced in it appears to be so efficient that respiration can be kept going normally for a considerable time after the respiratory centre has been completely paralysed. The main difficulty in the treatment of snake bite still remains, viz., getting the patient to hospital alive. Nevertheless, this case has demonstrated that if a case of colubrine snake bite can be put into the 'iron lung' while a vestige of life remains he can be kept alive long enough to allow antivenene to take full effect.

TWO FATAL CASES OF CARDIAC MALARIA

By S. K. SARKAR, M.B., B.S.

Assistant Surgeon, B. N. Railway, Dongargarh (C. P.)

CARDIAC malaria in the sense that the brunt of the attack falls on the heart and the patient suddenly develops symptoms of heart failure in the course of an ordinary attack of malaria is, I think, sufficiently interesting, and that is why I would like to report two such cases that I happened to meet with. I have been working in highly malarious areas for the last six years and have encountered various manifestations of malignant tertian infection, but no others with the symptoms that these two cases presented.

Case 1.—On 17th October, 1939, a young man, aged about 16, got a typical attack of malarial fever with ague and bilious vomiting. I prescribed atebrin for him (0.1 g. t.d.s.). He had no fever the next day, but the fever returned in the early hours of the morning of 19th. He had taken two tablets of atebrin on 18th, but none on the 19th. I saw the patient again at about 5-30 p.m. on the 19th. He was fully conscious, and had an anxious look. He was very restless and complained of pain all over the body, particularly in the region of the praecordium and beneath the sternum. There was no radiation of this praecordial pain. Breathing was very distressed. Extremities were cold, but the body was hot. No radial, brachial or facial pulse could be felt. Heart sounds were distinct and regular, but very fast. The borders of the heart could not be properly percussed out. The bases of the lungs had a few râles. The spleen and liver were palpable. I gave him a cardiazol injection immediately and a few minutes later one intramuscular injection of quinine and adrenaline. He died shortly afterwards.

On enquiry I learnt that this boy had developed these urgent symptoms at about 12 noon, but as he was conscious the father did not consider them to be of any significance.

Case 2.—On 12th December, 1939, I saw a woman of about 60 suffering from high fever accompanied with ague. Cinchona and alkaline mixtures were prescribed for her. At about 9 p.m., I was called to see her again. She was conscious, but very restless. Breathing was distressed. Extremities were cold, but the body was warm. No pulse could be felt anywhere. Heart sounds were weak and regular, but fast. No râles were heard at the bases of lungs. Liver and spleen were not palpable. I gave her a cardiazol injection. She died half an hour later. She had developed these urgent symptoms at about 6 p.m.

Discussion.—In the *Indian Medical Gazette* for March 1938, Manohar and Khosrawy described anginal pain in a case of malaria. In

that article they have quoted references about cardiac malaria in the literature. In these quoted cases, sections of the heart showed malarial thrombosis and cloudy degeneration of the muscle or cloudy swelling of cardiac muscle resembling that of acute diphtheria, or vascular thrombosis with fragmentation and necrosis of cardiac muscle. As I could not procure the original articles, I could not make out if this malarial thrombosis is due to plugging of cardiac capillaries with malaria parasites similar to what happens in cerebral malaria. Manson-Bahr (1940) mentions death from suddenly developed cardiac failure in pernicious forms of sub-tertian malaria due to the severe toxic fatty degeneration of the myocardium, but does not mention malarial thrombosis in cardiac malaria. Whatever the exact pathology, severe toxic fatty degeneration of the myocardium or malarial thrombosis, this suddenly developed heart failure is rare and a very dangerous complication of malignant tertian malaria.

Both these cases described above showed fairly large numbers of malignant tertian rings in their blood. In both cases no history of any infection that could leave a damaged heart was elicited from relatives. Both developed identical symptoms of heart failure in the course of an ordinary attack of typical malaria and died within a few hours. Both remained conscious up to the last.

My thanks are due to my chief for permission to report these cases.

A CASE OF GONOCOCCAL VULVO-VAGINITIS TREATED WITH M.&B. 693

By S. K. SARKAR, M.B., B.S.

Assistant Surgeon, B. N. Railway, Dongargarh (C. P.)

THE following case of gonococcal vulvo-vaginitis that responded very well to M.&B. 693 when other reputed drugs like septanilam and clinoestrol failed to have any effect.

Case note.—A girl aged about five was found by her parents to have a vaginal discharge on 4th September, 1939. Weak permanganate of potassium baths and lotio mercurochrome application were tried for a few days without any improvement. On 14th September, she was sent to Khargpur railway hospital where the discharge was definitely proved to be gonococcal by smear examination. There she was put on prontosil tablets (one twice a day). Discharge stopped after three days of prontosil therapy; but recurred after 24 hours. She came back from Khargpur with instructions to be treated with clinoestrol. Clinoestrol was started here (0.5 mg. tablets—half twice a day). As there was no improvement at the end of a week dosage was increased to one tablet twice daily. She continued

it for another fourteen days. Towards the end of this period painful engorgement and deepening of pigmentation of her breasts were noticed, but no improvement of the vaginal discharge was seen. Clinoestrol was then stopped, and septanilam (one twice daily) was given for seven days without any improvement. Septanilam was then stopped and M.&B. 693 was started after seven days, on the suggestion of my medical officer. Discharge stopped after the second day of M.&B. administration (one twice daily). It was continued in the same dosage for three days more, then one daily for another five days. Discharge has not recurred up to now, which is over four months.

My thanks are due to my chief for permission to report this case.

A CASE OF ENTERIC PNEUMATOSIS

By S. T. DAVIES

MAJOR, I.M.S.

Superintendent, Government Hospital, Calicut

THE following case of enteric pneumatosis (gas-cysts of the intestine) is reported in view of the rarity of this condition, although it gives rise to no symptoms and is said to be of no clinical importance.

The patient was a Hindu male, aged 35 years, with clinical indications for gastro-jejunostomy. As the abdomen was opened hundreds of gas-cysts (see figure) were found throughout the whole length of the small intestine except the last three inches; they varied from the size of a small pea to that of a grape, and were mostly sessile but many were pedunculated. Pressure on the sessile ones caused the gas to run under the serous coat of the intestine.

CEREBRAL MALARIA SIMULATING MENINGITIS

By JAGDISH NARAYAN, M.B., B.S.

*Civil Assistant Surgeon, Chatra Hospital,
District Hazaribagh*

B. M., a Mohammedan male, aged 24 years, cultivator by occupation, was admitted on 8th March, 1940, for the treatment of (i) high fever and (ii) acute headache; duration—three days.

History.—The patient had severe rigor followed by rise of temperature on the 6th March, 1940, at 6 p.m. The temperature showed remission on the 7th morning but again there was a sharp rise in the evening preceded by severe rigor, acute headache and backache.

Condition on admission.—General condition—fair; no anaemia, no cyanosis. Tongue—dry and coated. Bowels—constipated. Pulse—feeble, 130 per minute, regular. Heart sounds—normal. Lungs—moist sounds at the bases. Temperature—101°F. (axillary).

Treatment.—Blood films were taken for the examination of malaria parasites and the patient was put on

quinine sulphate mixture 5*i*, *t.d.s.*, each dose containing seven grains of quinine sulphate. Blood films showed ring forms of malignant tertian malaria parasites.

9th March. There was rigidity of neck and muttering delirium present with unusual cry at times. No response to external stimuli. Patient lying on back in semi-comatose condition.

Reflexes.—Superficial abdominal reflex absent. Knee jerks exaggerated. Kernig's sign positive. Extensor plantar reflex present. Temperature—101.4°F. (maximum).

Treatment.—(i) Soap water enema.

(ii) Quinine sulphate mixture 5*i* thrice daily.

(iii) Quinine bihydrochloride, gr. x in 2 c.cm. saccharose solution intramuscularly.

(iv) Lumbar puncture done at 4 p.m. to relieve pressure symptoms. The fluid was under pressure but clear. Microscopic examination did not reveal anything particular.

10th March. Temperature—100°F. (maximum). Muttering delirium and rigidity of neck present. Had a restless night.

Treatment.—(i) Quinine sulphate mixture 5*i*, *t.d.s.*

(ii) Alkaline glucose draught *ad lib.*

(iii) Quinine bihydrochloride, gr. x in 2 c.cm. in saccharose solution injected intramuscularly.

(iv) Sleeping draught one dose at bed time.

11th March. Temperature—99°F. (maximum). Rigidity of neck and muttering delirium persisted. Bowels constipated.

Treatment.—Same as previous day.

12th March. Temperature—98.4°F. (maximum). No more delirium present. Rigidity of neck also less.

Treatment.—Quinine sulphate mixture 5*i* three times a day.

13th March. Temperature—99.6°F. (maximum). Rigidity of neck and muttering delirium absent. The temperature rose after rigor and accompanied with headache and backache.

Treatment.—Quinine sulphate mixture 5*i*, thrice daily, each dose containing five grains of quinine sulphate.

14th March. Temperature—98.4°F. (maximum).

15th and 16th March. Temperature—98°F. (maximum).

Treatment.—Same as before.

17th March. Temperature—101°F. (maximum). The temperature rose in evening preceded by rigor, acute headache, and backache.

Treatment.—(i) Alkaline glucose draught *ad lib.*

(ii) Atebrin tablets, one *t.d.s.*

18th March. Temperature—101°F. (maximum) preceded by rigor, headache and backache; onset in the evening.

Treatment.—Atebrin continued.

19th March. Temperature—98°F. (maximum).

Treatment.—Same.

Total 15 atebrin tablets were given followed by plasmoquin treatment.

The patient remained in the hospital up to 28th March. He was afebrile and progressing favourably.

Features of interest in this case are :—

(i) Cerebral malaria simulating meningitis.

(ii) Failure of quinine both by mouth and injection to control the temperature.

(iii) Success of atebrin tablets in controlling the temperature.

No doubt pressure symptoms decreased after quinine injection but temperature was not controlled*.

* This fact is not clear from the notes.—Ed., I. M. G.

Indian Medical Gazette

FEBRUARY

GOITRE

IN a recent number we published a short paper in which were summarized the results of a questionnaire on goitre issued by an enterprising medical officer in charge of a dispensary in the Kangra district in the Punjab. The analysis of the replies he received seemed to indicate that the condition was widespread, varying considerably in incidence in different districts, but that no new or standardized form of treatment was being adopted. What particularly distressed the writer was that the surgical treatment of this condition was being neglected. What strikes us as being more serious is that the simple preventive and early treatment procedures which are of established efficacy are not being used to the extent that they might be, for, if they were, fewer patients would reach the stage where surgical treatment was indicated.

From time to time we have received communications from other parts of India, usually montane or sub-montane areas, reporting the prevalence, or making enquiries as to the aetiology and treatment, of endemic goitre.

One such enquiry led us to look up the recent literature on the subject especially with reference to goitre in India. In view of the quite considerable literature on the subject, which includes the *Indian Medical Research Memoirs*, No. 23, and the monograph, *The Simple Goitres*, both by Sir Robert McCarrison, it is remarkable how little real information regarding the public health aspects of goitre in India, its aetiology, and the treatment most suited to the prevailing forms of goitre is available. Sir Robert McCarrison claims to have shown that there are at least three common types of goitre and that the aetiology is probably not the same in each case. He has shown that a number of dietetic factors will influence the growth of the thyroid, and that in addition insanitary and unhygienic conditions tend to increase the ill-effects of unsuitable dietary, or even to produce thyroid hypertrophy *per se*. He has also shown the effect of iodine but has made a particular point of emphasizing that iodine is not the only factor in goitre production and cure. This is very probably true for there are certainly anomalies in the distribution of goitre *vis-à-vis* iodine content of soil, but it is also true that of the various combinations of factors that appear to play a part in the production of goitre the most commonly recurring one is iodine deficiency, actual or relative, in the soil and water,

and it would be a pity if, as a result of Sir Robert McCarrison's excellent researches which have had the stimulating effect of destroying complacency on the subject of the aetiology of goitre, we were to allow our attention to be distracted by vague generalities regarding improving environmental conditions and the standard of living from the established fact that iodine given systematically will usually reduce the incidence of endemic goitre.

Hospital and dispensary reports of the different provinces give some idea of the relative incidence of the disease in India. The largest numbers of cases are encountered in the United Provinces, especially in the districts of Gonda, Gorakhpur and Dehra Dun; in this province the average number of cases treated annually is about 100,000. In Bihar the annual hospital and dispensary returns indicate about the same incidence; in this province the largest number of cases come from Champaran districts. Assam (particularly Goalpara district), the Punjab (particularly Kangra district), and Bengal each show about 30,000 cases annually. From Madras, Bombay and other districts negligible figures are reported.

Colonel H. Stott, I.M.S., who made a special study of the disease in the hyperendemic areas, found that goitre was rare below the age of 3 years. Between 3 and 5 years the rate is less than 5 per cent, though the percentage rises higher in severely affected areas. The incidence is 10 to 20 per cent between 6 and 14 years, but the rate may reach 80 per cent in areas of greatest endemicity. Between 15 and 30 years the rate rises to 60 per cent, but falls again above 30 years. He further reported that very few educated and well-to-do persons suffer from this condition, which is definitely more prevalent among females; for every one male roughly three females are affected.

The term 'goitre' is applied in a general way to any visible enlargement of the thyroid gland of a non-inflammatory and a non-malignant nature. The most physiological form of thyroid enlargement is simple goitre which results from the compensatory hyperplasia of the thyroid and is not associated with obvious symptoms of deficiency or excess of secretion. The condition is endemic among adolescents, especially among young girls, who reside in certain localities, including districts where the iodine supply in the drinking water, soil, and vegetables is inadequate for physiological needs; the symptoms are most prominent among this group, because the iodine supply becomes insufficient only when the biochemical changes associated with puberty, menstruation, pregnancy, lactation and emotional strain demand increased thyroid activity. Sporadic cases of simple goitre may develop in iodine-rich districts following infections, intoxications or strain, which reduce the efficiency of the thyroid tissue, which divert from the thyroid gland its normal quota of iodine, or which in other ways necessitate an extra supply of

thyroxin. In general, the areas of high endemicity are found in mountainous country or remote from the sea. Some of these regions are old ice-fields where most of the iodine has been leached from the soil.

Heredity is also a factor, for the incidence in endemic districts is higher among the offspring of goitrous parents and is greatest when several generations of ancestors have been goitrous. The onset, or an exacerbation of signs and symptoms, is frequently observed in association with infective diseases such as tonsillitis and influenza. Animal experiments suggest that other factors may be found in unsuitable diets and in general unhygienic conditions, and the recently discovered thyrotropic hormone in the anterior lobe of the pituitary, which on injection into animals produces hypertrophy of the thyroid gland, may be an important clue to the causation of the disease. All these forms of experimental goitre can, however, be prevented by a sufficient supply of iodine.

There has also been evidence suggesting that goitre occurs in people who drink water contaminated with something which does not pass through a porcelain filter, and which is destroyed by boiling the water; these observations suggest, but do not prove, that one of the exciting causes is microbial. Experimentally it has been shown that an enlargement of the thyroid gland follows the ingestion of the residue on a filter through which goitrogenous water has passed. It is possible that the bacteria may absorb the iodine before it can be taken up by the thyroid, and in this way produce simple goitre, rather than by their direct toxic action on the gland. The greater the contamination of the water, the greater is the amount of the iodine necessary to prevent the disease.

Thus, it appears that a combination of factors is responsible for incidence of the disease. But it will be noticed that, though investigations have led us into devious paths, these paths lead us back to one point, namely, shortage, absolute or relative, of iodine. Endemic goitre may therefore be regarded as a deficiency disease; this has received confirmation in the successful prophylactic use of iodine in various endemic areas.

Two methods of iodine administration are practised : (a) The admixture of a small percentage of iodine with table salt, sodium or potassium iodide being added in the proportion of about 1 in 200,000; as a public health measure in some countries where endemic goitre is common, all table salt offered for sale has to contain this amount of iodine; and (b) the administration of iodine to school children, the dosage being about 3 grains of potassium iodide daily for ten days twice a year, in spring and autumn. Higher doses are in excess of requirements and wasteful. Iodine should also be given in a similar dosage to women during pregnancy and lactation. The latter method has proved successful in America.

The results of such prophylaxis have been shown to be so excellent that endemic goitre may now be ranked as one of the few diseases that medical science has really mastered. One of these methods should certainly be adopted in all the endemic districts of this country where some such measure is not already in operation, and in controlled labour forces, such as those of tea gardens, this should present no difficulties.

The treatment of established simple goitre is less satisfactory than the prophylaxis; prevention is once again better than cure. Administration of iodine should be given a trial; it may prove successful, but diminution in the size of the gland is by no means the rule. Then the question of the danger of provoking hyperthyroid symptoms by the ingestion of excessive quantities of iodine arises, and, though it has never been definitely shown that this occurs, it is advisable to be cautious in the treatment of simple goitre particularly in subjects with a nodular gland, and patients should be discouraged from taking it on their own initiative without reference to their medical advisers. When iodine fails to effect improvement, thyroid should be given, *under strict medical supervision*. This will usually lead to the disappearance of any symptoms of hypothyroidism, but as far as the diminution in the size of the gland is concerned the results are uncertain. Surgical treatment should only be considered—if symptoms of thyrotoxicosis develop, if the gland is nodular, if malignant changes are suspected, if pressure symptoms arise, or if the swelling is disfiguring.

Graves' disease presents a more complex problem, both in its aetiology and in its treatment. In this condition the thyroid secretes thyroxin far in excess of the needs of the organism. There is no known aetiological relation between this condition and endemic goitre, and in fact in areas of endemic goitre it is no more common than in the ordinary population. It is not due to iodine deficiency, although iodine administration brings at least some temporary improvement. The precise cause of this condition is yet unknown. There is a good deal of controversy on the point. Some workers consider that the disease originates in the thyroid gland, and the local therapeutic measures adopted by the surgeons and roentgenologists are in keeping with this view. Others consider the thyroid involvement to be part of a general constitutional disorder associated with widespread dysfunction of the autonomic nervous system. It is also possible that the essential disturbance is an excess of the thyrotropic hormone of the anterior pituitary gland.

Mental trauma such as domestic or financial worry, anxiety, or shock, not infrequently with a sexual association, are often suggested as exciting causes. However, the thyrotoxic subject is a restless, nervous and 'highly strung' individual, and one does not know how far this condition is the cause of, or the result of, the Graves' disease. The great war did not appear

to cause any increase in Graves' disease; it will be almost conclusive proof that mental trauma plays little part in its aetiology if there is no increase in England under present conditions.

The treatment of Graves' disease involves the institution of a broad regime of therapy involving hygienic, dietetic, medicinal, psychotherapeutic and/or surgical measures. Most cases require full study and careful assessment before the line of treatment can be decided upon. For instance, mild thyrotoxic symptoms in a young girl will often disappear on solution of some family or emotional problem, whereas a middle-aged woman with a nodular gland is referred for operation as soon as possible. In other cases, the patient on account of a high metabolic rate will require absolute rest, both physical and mental, for a few months, with sedatives such as phenobarbitone, and probably iodine as well. The effect of iodine is not curative, but it holds the symptoms and basal metabolic rate in check, and causes the disease to run its course at a lower level of activity. It is given as Lugol's solution in 10 minim doses (equivalent to 1 grain iodine) or preferably as potassium iodide in $1\frac{1}{2}$ grain doses three times a day. Incidentally, there is much to be said for the substitution of potassium iodide for Lugol's solution. The full effect is usually obtained in ten to fourteen days. Subsequent progress will depend on whether or not the remission has set

in. If it has started, a steady improvement may continue; but, if the disease is still progressing, iodine should be continued for weeks or months in smaller doses (half or even less). The prolonged administration of iodine is however not approved by the surgeon. If operation is contemplated, it should be carried out as the remission sets in. The difficulty arises in pre-operative management of cases who have been given iodine for prolonged periods. Most surgeons prefer freshly-iodized subjects and will not operate unless an iodine-free period of 6 to 8 weeks has elapsed immediately before the pre-operative iodine treatment.

Radiotherapy has been practised for many years; there is much controversy as to its usefulness, but recent claims have been made that it can replace surgical treatment in 75 per cent of cases, and it is undoubtedly less risky. However, if a case does not show considerable improvement within 3 months, radiotherapy is not likely to be successful.

Thyroid extract is obviously contraindicated in such cases. We publish elsewhere in this issue the report of a case of primary Graves' disease in which thyroid in increasing doses had been prescribed, with very unfavourable results. 'To administer thyroid substance to the patient with Graves' disease is tantamount to pouring gasoline on a conflagration'.

(13) The Arneth and Schilling counts

ARNETH (1904) divided the neutrophil polymorphonuclears into five main classes according to the number of segments in the nuclei which in their turn were classified into various groups according to the shape of the lobes. Under the original classification the count was very complicated and had only limited application in general practice. Cooke and Ponder (1927) modified and simplified the Arneth count taking into account only the five original basic divisions of the Arneth count without going into the intricate subdivisions of Arneth.

Schilling devised a method in which the differential leucocyte count and a simple nuclear lobe count of the neutrophils were incorporated and considered in the form of a 'hæmogram'.

Apparatus required (vide part VI).

Smears.—Smears for the Arneth and Schilling counts should be very thin and uniformly

spread; they should be dried quickly by waving them to and fro under a fan (*vide part VI*).

Staining.—Combined staining with May-Grünwald and Giemsa stains gives the most satisfactory result—the nuclei stain deeply, the connecting chromatin filaments are well shown, while the granules also show characteristic colour and size. If May-Grünwald and Giemsa stains are not available, proper staining with Wright's or Leishman's stains, though not as satisfactory, gives quite good results. Iron-hæmatoxylin or hæmatoxylin staining for these counts in preference to any of the Romanowsky stains is sometimes advocated; while these stains bring out the nuclei and the chromatin filaments well, the colour of the granules is not distinctive so that differentiation between neutrophils and eosinophils is very difficult.

A. Arneth count

The nucleus of the neutrophil polymorphonuclear cells is divided into lobes which may be separate or joined together by fine filaments of chromatin. Cooke's criterion of separate lobulation is that either the lobes should be distinctly separate, or should be joined together by a fine chromatin filament, but not by broad bands of nuclear material. Lobulation of the nucleus, it

is assumed, gives an indication of the age of the cell—the less the lobulation the younger is the cell. The youngest cell in the normal peripheral circulation is one which has a nucleus shaped like the letter C, while the cells with five or more distinct nuclei are the oldest. The principle of the method is to make a differential count of the neutrophil cells, to group the cells according to the lobulation of the nuclei, and to calculate the percentage of cells in each group.

The cells of the various types can be described as follows :—

Class I. Neutrophil granulocytes in which the nucleus has only one definite lobe, or two or more lobes joined by a definite band of chromatin and not by thin filaments.

Class II. When there are two separate lobes joined by one thin filament, or when there are two completely separate lobes.

Class III. When there are three separate lobes connected by two thin filaments, or there are three completely separate lobes.

Class IV. When there are four separate lobes connected by three thin filaments, or there are four completely separate lobes.

Class V. When there are five or more separate lobes connected by four or more filaments, or there are five or more completely separate lobes.

The count is made by identifying and classifying one hundred neutrophil granulocytes from different parts of the slide, and the result is usually reported in the following form :—

Example 1, a normal count

Class	I	II	III	IV	V	Total
Number	10	25	47	16	2	100

When there is an increase in the number of cells with one and two separate nuclear lobes, i.e., of class I or class II, at the expense of those with three or more lobes, there is said to be a 'left shift' in the Arneth count, as in the example given below :—

Example 2, a 'left shift' count

Class	I	II	III	IV	V	Total
Number	41	44	14	1	0	100

Conversely, when there is an increase in the 4- and multi-lobed nuclei, it is known as a 'right shift'.

Example 3, a 'right shift' count

Class	I	II	III	IV	V	Total
Number	9	22	36	23	10	100

Various indices and methods of expressing more concisely the results of the Arneth count (Cooke's modification) have been proposed. Probably the most suitable of these methods is the calculation of the weighted mean of the nuclear lobes; this is obtained by multiplying the number of cells in class I by 1, the number in class II by 2, the number in class III by 3, the number in class IV by 4, the number in

class V by 5, and then adding together and dividing the sum total by the number of cells counted.

The weighted means of the nuclear lobes in these three examples are calculated in the following way :—

Example 1	Example 2	Example 3
$1 \times 10 = 10$	$\times 41 = 41$	$\times 9 = 9$
$2 \times 25 = 50$	$\times 44 = 88$	$\times 22 = 44$
$3 \times 47 = 141$	$\times 14 = 42$	$\times 36 = 108$
$4 \times 16 = 64$	$\times 1 = 4$	$\times 23 = 92$
$5 \times 2 = 10$	$\times 0 = 0$	$\times 10 = 50$
100	100	100
275	175	304
Weighted mean = 2.75	1.75	3.04

Interpretation.—Immature granulocytes and cells of Arneth class I and some of class II, but none of class III, IV or V, are found in the bone marrow. If there be a sudden stimulus to the bone marrow to produce granulocytes, as in an infection, the leucocytosis is brought about by young cells appearing in the blood, the number and the proportion of these depending upon the nature of the stimulus and the reacting power of the marrow of the individual, and there is a shift to the left in the Arneth count. But leucocytosis as a result of muscular exercise is only due to redistribution of cells, is not accompanied by any increase of young leucocytes in the peripheral circulation, and is therefore not associated with any 'left shift'.

Again, in chronic infection or toxæmia, there is an increased leucocyte destruction, which may or may not be balanced by new leucocyte formation; in the former case there will be leucocytosis or a normal count and in the latter leucopenia. In either case there is an increase in young forms, actual or relative, which results in a shift to the left and a decrease in the weighted mean. It will be apparent that this shift is quite independent of the total leucocyte or total granulocyte count, and provides another 'angle' on the degree of the toxæmia.

In pernicious anaemia and certain other conditions of bone marrow dysfunction, there is a shift to the right in the Arneth count, and therefore an increase in the weighted mean; in such conditions there are many multi-lobulated

Normals

	I	II	III	IV	V	Weighted mean
Cooke and Ponder (1927)	10	25	47	16	2	2.75
Kennedy (1933) (Iraq)	13	30	43	10	4	2.62
Das Gupta (Calcutta)	40	43	15	2	0	1.79

cells and only very few young cells coming into the circulation.

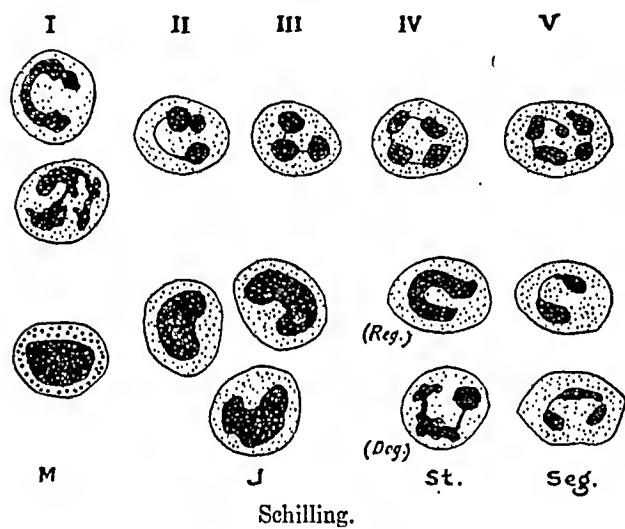

B. Schilling count

In this count the neutrophil granulocytes are divided into four groups and classified as follows :—

1. Myelocytes (M).
2. Juveniles (J); these have a distinct indentation in the nucleus; they correspond to our meta-myelocytes.
3. Stab cells (St); these have a C- or horse-shoe-shaped nucleus but no true lobulation; they correspond to class I of the Arneth count, and to our staff cells.

Stab cells may be of the regenerative or degenerative type, and are differentiated by the shape and staining reaction of the nucleus; in the latter the nucleus is ribbon-like and pycnotic with clumps of chromatin, and usually irregular shaped, and the cytoplasm may be vacuolated.

Arneth.

Schilling.

4. Segmented (S) polymorphonuclears, showing two or more distinct lobes.

According to Schilling the following are the constituents of a normal haemogram.

Total	Percentages								
	W.B.C.	B.	E.	M.	J.	St	Seg.	L.	Mon.
5,000 to 8,000	0-1	1-2	0	0-1	3-5	57-67	21-35	4-8	
			60-70		

B. = basophil. E. = eosinophil.

L. = lymphocyte. Mon. = large mononuclears.

Discussion.—The Schilling haemogram is much more than a differential granulocyte count, as is the Arneth count, and Schilling claims that it gives far more information. The interpretation depends on a highly imaginative series of responses to infection and toxæmia that are supposed to, and possibly do, occur in the haemopoietic system in which there are three

phases, neutrophilic struggle, monoeytic defence, and lymphoeytic cure, but it does not seem to take into account the nature of the infection and the consequent variations in the response. Further, there are so many directions in which changes may take place, that the haemogram seems peculiarly susceptible to facile interpretation to suit the conscious or unconscious wishes of the interpreter.

We do not propose to give a full disscussion on the interpretation of the haemogram, as it has only an indirect bearing on the subject of anaemia, but, as far as the neutrophil granulocyte elements are concerned, Schilling's contention is that infection may cause two types of reaction, the regenerative reaction and degenerative reaction; in the regenerative reaction, new leucocytes are formed in the bone marrow and this is reflected in the peripheral circulation by a rise in the total white-cell count, an increase in the juveniles and regenerative forms of stab cells, while in the degenerative reaction, which is found in severe toxæmia, on account of the degenerative influence of the toxin on the marrow, the formation of new cells is retarded; this may be shown by a leucopenia. In the differential count of such a case there are few juvenile cells, and the stab cells that reach the circulation fail to segment at the usual rate, and may degenerate with the result that there is a preponderance of stab forms, including many degenerative forms, in the blood. The reaction, however, may not be purely regenerative or degenerative in character, but may be a mixture of the two, and the haemogram may be intermediate, with slight leucopenia and a greater preponderance of the younger cells than in a purely degenerative process.

(It is surprising to the writers that no provision is made in the classical Schilling haemogram for the separate counting of the regenerative and degenerative forms of stab cell, when obviously the presence or absence of the latter is an important factor in the interpretation of the haemogram.)

Conclusion.—The interpretation of the Arneth count is simpler, though the implications are more limited, but it presents a minor practical objection in that more skilful staining is required to ensure accurate counting of the separate lobes.

The value of these counts is mainly in establishing the presence of infective or toxæmic factors, which may be important contributory causes of the anaemia, and/or may prevent response to appropriate haematotics. The presence of multi-lobular cells, shown only in the Arneth count, is important in the diagnosis of pernicious anaemia.

(14) *The erythrocyte sedimentation rate*

The determination of the erythrocyte sedimentation rate (ESR) is not a test that gives much direct information regarding the nature of the anaemia, but it is of value in differentiating

'functional' disorders, such as pernicious anaemia in which the true ESR is within normal limits, from anaemia due to such causes as sepsis and malignant disease in which the ESR is markedly increased.

Further, the ESR is affected by changes in the shape and size of the red cells, in so far as these changes affect rouleaux formation, and by changes in the concentration of the red cells in the plasma; this last may overshadow the other changes and, being a measurable factor, must be allowed for in estimating the true sedimentation rate.

Finally, as from the single specimen taken in the normal course of a routine blood examination the ESR can be estimated without additional labour, it should always be included.

The test suffers from the multiplicity of the methods by which it is performed and by the variety of the forms in which the results are expressed. The most commonly used technique is that of Westergren (1926), but, as it is important that the correction for anaemia should be made and as no correction chart has been worked out for this technique, this method has its limitation.

Wintrobe's method (1933) is really a modification of this method; it has the advantage that the cell volume can be estimated on the same sample of blood and also that a correction for anaemia can be made.

Principle of the test.—A known volume of blood is intimately mixed with a definite amount of anti-coagulant, and the mixture is drawn into a tube of known calibre up to a certain point; the tube is then allowed to stand in an upright position at room temperature and the level of the red blood cells in the tube is noted at the end of one hour and again after two hours. The fall in the level of the red cells is expressed in millimetres.

Westergren's method

Apparatus required—

I. Sedimentation tubes.

Westergren tube. This is about 300 mm. long and is graduated from 0 to 200 mm. in 1 mm. intervals; it has a uniform bore of about 3 mm. and is open at both ends.

II. Special Westergren rack, or an improvised rack, to keep the tubes in a vertical position, and to prevent the blood escaping.

III. Anti-coagulant:—3.8 per cent sodium citrate solution.

IV. Syringe, etc., for collection of blood.

V. Stop watch.

Technique.—In this method 3.8 per cent solution of sodium citrate is used as anti-coagulant in the proportion of one part of citrate solution to four parts of the blood.

Put exactly 2 c.cm. of blood into a flask to which 0.5 c.cm. of 3.8 per cent solution of sodium citrate has already been placed. Mix immediately by rotating the flask and subsequently if possible in a shaker; then draw up the mixture into a Westergren's standard tube to the zero mark which is exactly 200 mm. from the tip.

The tube is now set upright in a stand in which a spring clip holds the points of the tube firmly against a rubber cork at the bottom end. The tube is now left to stand and the upper level of the red cell column, which is generally sharp, is read at the end of one and again after two hours*. The length of the column of plasma from the zero mark to the top of the red cell column is the amount of sedimentation and this is read off in millimetres; this is reported as the sedimentation rate in millimetres for one hour and for two hours.

Normal limits (after one hour)—

	Men	Women
Textbooks	3 to 5 mm.	4 to 7 mm.
Our own experience in Indians in Calcutta.	3 to 15 mm.	5 to 40 mm.

The high figures that we obtained in apparently normal subjects are partly explained by the higher temperatures that prevailed, compared with those of the places where the tests on which other normal figures are based were carried out.

Wintrobe's method

Apparatus required—

I. Wintrobe's tubes—a flat-bottomed glass tube 100 mm. long graduated from 0 to 100 in 1 mm. intervals; it has a uniform bore.

II. Anti-coagulant—sodium and potassium oxalate mixture (*vide* part I).

III. Electric centrifuge.

Together with a syringe and stop watch as in Westergren's method.

Technique.—Wintrobe used his cell-volume tube for the determination of the sedimentation rate.

The blood is collected in an 'oxalated' flask and is thoroughly mixed; the cell-volume tube is filled with the oxalated blood by means of a capillary pipette up to the zero mark, which is exactly 100 mm. from the bottom. The tube is now allowed to stand upright in a vertical position on a special stand or on a tray of plasticine, and the reading is taken at the end of one and again after two hours*, in the same way as in Westergren's method; the cell-volume tube is then put into a centrifuge and centrifuged at 3,000 revolutions per minute for half an hour to obtain the packed cell volume percentage; thus both procedures are done in the same tube with the same blood sample.

Normal limits (after one hour)—

	Men	Women
Textbooks	0 to 9 mm.	0 to 20 mm.
Our own experience in Indians in Calcutta.	2 to 20 mm.	2 to 30 mm.

Correction for anaemia.—One important factor in the rate of sedimentation of bodies in fluid is the concentration of these bodies. The sedimentation standards for red cells in plasma are based on there being a normal number of red cells in a given volume of blood, and in anaemia when these are reduced the sedimentation rate is increased above the normal irrespective of the other changes in the blood. To make the correct allowance for this fact Hynes and Whitby

* Only one-hour readings are usually recorded.

(1938) worked out a chart showing the relationship of cell volume and sedimentation rate in normal blood and in blood showing various degrees of anaemia; this chart is reproduced below.

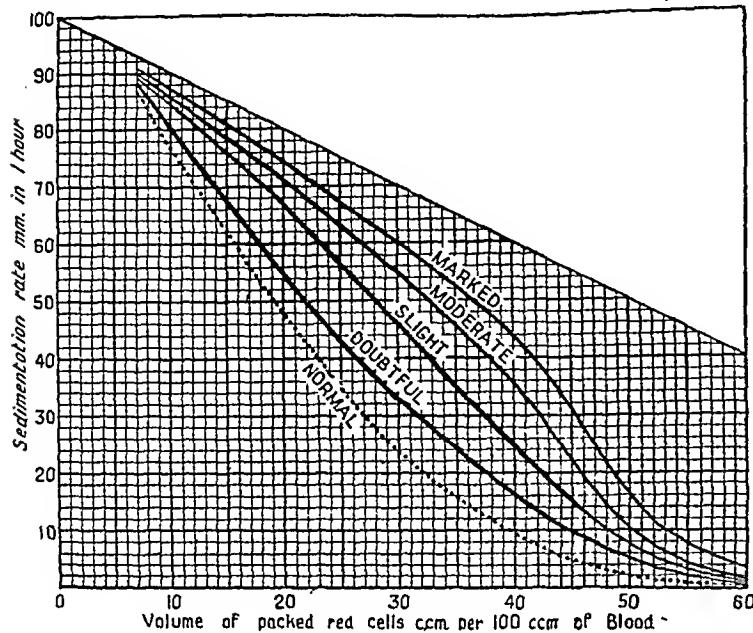

Chart for correction of sedimentation rate for anaemia by means of the corpuscular volume.

To correct for anaemia, find the junction of the lines of the observed sedimentation rate and the observed corpuscular volume; this point will fall in one of the five zones (normal, doubtful, etc.) which indicate the approximate degree of increase in the rate. If a 'compensated' figure is required, follow the appropriate curve down to the point where it cuts the 45 c.cm. vertical lines, for men, and the 40 c.cm. line for women.

Example: Observed rate = 50 mm.; observed corpuscular volume = 30 per cent; point of junction lies in area of 'slight' increase; compensated rate for men = 18 and for women = 28.

Precautions

- (i) All apparatus must be scrupulously clean and dry.
- (ii) The dilution with sodium citrate solution in Westergren's method should be absolutely correct.
- (iii) The specimen of blood should be collected during the fasting state and examined within one hour of collection.
- (iv) In women it is advisable to avoid the menstrual period and the few days before and after it.
- (v) The specimen should be rejected if there be a slight trace of coagulation or any marked haemolysis.
- (vi) The tubes should be set up in an absolutely vertical position in a quiet place, well away from any apparatus that vibrates. The temperature of the room should be between 72° and 80°F. whenever possible.
- (vii) In recording the results, correction for anaemia must always be applied.

Discussion.—There are a number of factors involved in the phenomenon of erythrocyte sedimentation, but the most important is the size of the rouleaux formation and this is mainly determined by the composition of the plasma.

Increase in plasma fibrinogen will cause an increase in the size of the rouleaux formation and therefore an increase in the sedimentation rate. It is probably on this fact that the value of this test depends, as, with the exception of the concentration of the red cells for which allowance can be made, this effect overshadows all others.

The sedimentation rate is increased in so many conditions that it is very dangerous to attach any specific diagnostic significance to it. This must be quite obvious from the wide range of the ESR rates that has been recorded in apparently healthy individuals. However, the ESR is a test of great value in estimating the progress in chronic infections, such as tuberculosis and leprosy. A standard technique should be adopted, and in reporting the results the method employed must be stated or the information loses much of its value.

ON THE CHOICE OF DRUGS IN THE TREATMENT OF BACTERIAL INFECTIONS

By A. CHAKRAVARTI, F.R.C.P.E., F.R.S.E.
and

U. P. BASU, D.Sc., F.R.S.

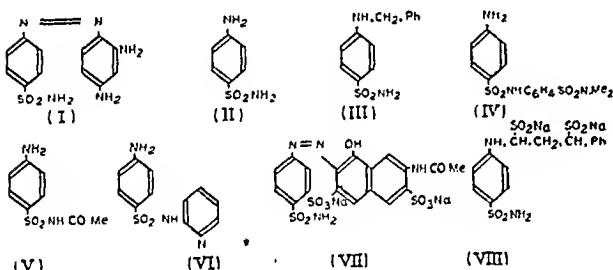

(From the Bengal Immunity Research Laboratory, Baranagore, Calcutta)

THE extensive investigations carried out during the last 5 years with experimental animals, as well as in the clinical fields, have afforded to the physicians a number of organic sulphur-containing substances for combating the various bacterial infections. The value of this chemotherapeutic treatment with sulphanilamide, or its derivatives, is now beyond question. Physicians, however, should be fully cognizant of the fact that these compounds

possess not only extraordinary therapeutic activity but at the same time exert a wide range of toxic manifestations, some of which are mild and may be safely ignored, while there are others that are of serious type and if not heeded in time may even endanger the life of their patients. Obviously, it would always be a sound practice to find out the causative agents of the disease before instituting this drug therapy. The well-known method of treatment by the long established immunotherapy should also not be totally ignored, particularly when the clinical diagnosis and special considerations regarding any individual patient warrant it.

Chemical nature

A scientific discussion, therefore, on the rational use of the various drugs that are now available in the market seems likely to be of interest. The most common products are 4'-sulphonamido-2, 4-diamino-benzene (Domagk's compound I), sulphanilamide (II), benzyl, sulphanilamide (III), sulphanilyl-dimethyl sulpha-nilamide (IV), sulphanilacetamide (V), 2-sulphanilamido pyridine (VI)—all for oral use, and Neoprontosil (VII) and γ -phenyl-propyl-amino phenyl sulphonamide α : γ -disodium sulphonate (VIII) for parenteral administration.

From the above structural formulae it would be evident that all are derivatives of the compound (II)—p-amino-benzene sulphonamide—the most widely used drug of the series. It is active against haemolytic streptococci of groups A, B and C, and meningococci, less so against gonococci, and possesses no specific action against the pneumococcus, with the exception of type III. By substituting the p-amino grouping by one or other radicle or any chain, either its solubility as in (VII) and (VIII) may be increased or the toxicity as in (III) may be lowered. On the contrary, when the hydrogen atom of the sulphonamido group is substituted by any other group, its range of activity is considerably widened as evident from the compounds (V) and (VI) which were also found to be efficacious against pneumo- and gonococcal infections.

General consideration

The question arises what type of compounds is to be selected for a particular treatment and again how the course is to be planned. At the very outset, it may be pointed out that the type

of infecting micro-organism, as well as the severity and place of infection, is of primary importance. Other clinical considerations, such as age, secondary infections or physiological disorders, are also not to be brushed aside. Infants and children generally tolerate the drug more easily than the aged. The infections of soft tissues are better controlled than those of the bones. The patient receiving this drug treatment should be seen daily by his physician, and, if this be not practically possible, then the instruction should be laid down to record the body temperature once in the early morning and once in the evening, and to watch for any nausea or vomiting. This might help in the detection of the side reactions associated with the drug therapy. Further, it is preferable that the haemoglobin and the total white blood cell count of the patient should be ascertained at least twice a week. The ideal method would be to study the concentration of the drug in the blood and other body fluids. A concentration of 5 mg. of the drug per 100 c.cm. of the blood is sufficient to kill the invading organisms in milder infection, whereas a 10 to 15 mg. concentration might be necessary in severe infections of haemolytic streptococcus, meningococcus, gonococcus or pneumococcus. Long, Bliss and Feinstone (1939) have drawn up charts indicating the dosages that might be required for persons of different ages and that again with different types of infections. There are so many factors in this new drug therapy that it is very difficult to chalk out a correct dosage for each and every type of patient. The time required for absorption of the drug, the liver's function to convert the drug to a comparatively less effective product by acetylation of the para-amino grouping, and the rapidity of excretion are the factors that hinder any generalization on the mode of dosing. The four-hour dosage schedule is very important for the fact that the maximum concentration of the drug in the blood has invariably been found to be reached within this period. The individuals who are found not to absorb the drug to the proper concentration, should be treated with higher doses. But as soon as the patient is feeling better and when his temperature has subsided, the dose may be gradually reduced from say 12 tablets to 6 and then to 3 tablets (6 gm. to 1.5 gm.). But it should be very judiciously continued till the patient is completely cured as continuous administration of the drug may give rise to toxic symptoms and even agranulocytosis.

If again the patient be suffering from renal disorders, every measure should be taken for the effective elimination of the drug within a reasonable limit (i.e., within 48 to 72 hours). This is of special significance from the fact that non-excretion of the drug may increase blood concentration and thereby produce the characteristic side reactions. Excess of fluids might help in urinary output and the consequent excretion of the drug, but too much liquid by inducing rapid

solubility would facilitate easier and earlier absorption of the drug in the blood and thereby might again promote toxic manifestation. In adults, 6 pints in all will be found to be adequate and it should be decreased according to age. On the basis of the observations of Snodgrass and Anderson (1937) it has been the general custom to place a restriction on the diet. No excessive dietary restrictions (even eggs or onions not excepting) is necessary, unless the nature of infections or the condition of the patient demands it (Banks, 1939). Of course no saline purgative should be given; oils, liquid paraffin, or an enema may be administered for the movement of the bowels. Regarding the toxic manifestations it may be said that these mostly occur on a basis of sensitivity or idiosyncasy. Most of the side reactions of pure sulphanilamide therapy are of milder nature and can be safely avoided (Basu, 1940). It creates an acidosis by increasing the excretion of sodium and potassium in the urine and for this every dose of the drug should be given with sodium bicarbonate (total daily dose being 3 to 3.5 gm.). The other common toxic manifestation is the production of a type of cyanosis owing to the formation of methaemoglobin (Wendel *et al.*, 1939) and it may be removed even when found to be severe, by injecting a one per cent solution of methylene blue (0.1 to 0.2 c.c. per kg. of body-weight) (Wendel, 1939).

Pharmacological and physiological characteristics

Sulphanilamide.—The biochemistry of sulphanilamide has been more thoroughly studied. It is found to be evenly distributed throughout the body (Marshall *et al.*, 1937). This simpler compound is being successfully used in streptococcal tonsillitis, pharyngitis, acute otitis media, and mastoiditis with lesser dosage. With a more heroic dosage the drug is effecting wonders in erysipelas, cellulitis, puerperal fever, and streptococcal and meningococcal meningitis. For the prevention of clinical acidosis, it should always be administered with sodium bicarbonate. Ingestion of glucose also favours its tolerance.

It is the duty of the physician to decide whether any surgical treatment is essential in a condition of erysipelas or cellulitis for the removal of any focus of infection, or for letting out pus. The drug should always be given in the puerperium even as a preventive measure, or at least with the first sign of infection. In meningitis the patient should be treated with a very heavy dose and his blood and spinal fluid concentration should be determined. Further, spinal fluid cell counts would be valuable aids in ascertaining the progress of the infection and thereby helping in regulating the doses of the sulphanilamide. In cases where such a study is not possible, the general clinical response of the patient would be a good guide to the physician. Sulphanilamide is also a good urinary antiseptic;

but in any treatment of the urinary tract infections balance between the intake of the drug by mouth and its output in the urine must always be maintained. Precautions for any renal disorders must be observed and a knowledge of the amount of the blood non-protein nitrogen will be a guide in this direction. Under normal conditions, 10 tablets (5 gm. in all) with almost two-thirds the amount of sodium bicarbonate is the corrected daily dose. Though this simpler and cheaper product is effective against so many infections, it is not so efficacious in gonococcal and pneumococcal infections. For the former the compounds (IV) and (V) are being largely used, and in the latter case sulphapyridine (VI) gives better result.

Sulphanilacetamide (V).—Sufficient clinical evidence is on record that tends to show that the compound sulphanilyl sulphonamide (Grütz, 1937; Felke, 1938; Shelley, 1939; O'Crowley *et al.*, 1939) is potent against gonococcal infections. But it is less soluble and consequently less rapidly absorbed from the gastro-intestinal tract. Its clinical use is, again, restricted on account of the fact that it often gives rise to peripheral neuritis (Freusberg, 1938; van Valkenburg and von dem Borne, 1938; Bannick *et al.*, 1938). On the contrary, the compound p-amino-benzene sulphonyl acetamide (V) is found to be less toxic and easily tolerated (Dohrn and Diedrich, 1938; Vonkennel and Korth, 1938). In our observations, even total oral doses of 100 tablets (50 gm.) in about 2 weeks did not produce any untoward symptoms. It is absorbed from the intestine and is excreted in the urine within 72 hours. It is always found to be a better drug in the treatment of gonorrhœa.

Sulphapyridine (VI).—In pneumococcal infections this compound should be the drug of choice. It does not produce acidosis and is less likely to produce methaemoglobin. It is, however, irregularly absorbed and slowly excreted (Hobson and MacQuaide, 1938; MacLeod, 1939). When again the excretion is impaired owing to any renal damage or for any other cause, the drug is more acetylated in the system and this latter derivative being poorly soluble is precipitated in the urinary tract with resultant urinary obstruction and subsequent development of pyelonephritis. Smith *et al.* (1940) further observe that the crystallization of the acetyl sulphapyridine in the urine may even help in the development of renal calculi. The drug is found to produce a more severe mental and physical depression (Finland *et al.*, 1939). It should not therefore be given to patients with jaundice, or liver or kidney disease. Another side effect of the drug is the production of intense nausea with vomiting (Anderson and Datta, 1939; Bensley, 1940). Sulphanilamide also causes nausea and vomiting, but these are seldom found to be severe. In view of all these observations, particularly for the occurrence of renal damage, the treatment with this drug must be regarded as potentially dangerous and must be avoided.

in treatment of patients suffering from diseases other than pneumococcal pneumonia. In this latter dreaded disease the compound is really a very potent drug. But in a tropical country, such as India, pure pneumococcal infections are comparatively rare. Still a detailed study of the bacteriology of the pneumonic or bronchopneumonic condition, and the typing of the infecting bacteria, seems to be of considerable interest. This is of special significance for the fact that if the infection be due to type III, it is quite amenable to the treatment with simple sulphanilamide when again followed up with serotherapy (*vide infra*).

There are two other drugs, sulphonamido-2:4 diaminobenzene (Prontosil Rubrum, I) and benzyl sulphanilamide (III). The former is now of only historical interest and in the opinion of Whitby (1938) the preparation is almost obsolete. The other compound is less toxic than sulphanilamide, but at the same time less efficacious too. On account of its safety, it may be prescribed in milder streptococcal infections. In severe and urgent cases sulphanilamide (II) is the drug of choice.

The two sodium salt derivatives (VII) and (VIII) are of interest for their enhanced solubility. When an immediate effect is necessary, when it is difficult for the patient to swallow the tablet products, when nausea and vomiting are pronounced, or when the conditions do not allow a proper concentration of the drug in the blood, they may be parenterally used. In cerebrospinal infections the red variety (VII), however, penetrates from the blood to the theca more slowly than sulphanilamide (Jauerneck and Gueffroy, 1937). Further, in urinary infections the excreted product is only a urinary antiseptic, in so far as the compound has been reduced to colourless sulphanilamide. In these respects, however, the other compound is invariably being found to be clinically more effective in streptococcal and meningococcal infections. It has also been reported to be efficacious in influenzal meningitis (Teggart, 1938). It is more rapidly eliminated in the urine and always well tolerated, whether injected subcutaneously, intramuscularly, or intravenously, in comparison with the red solution. In meningococcal infection, repeated administration at short intervals is important. The activity of the product is undoubtedly due to the rapid liberation of sulphanilamide in the circulation.

Synergy treatment

The treatment of bacterial infections by means of the various synthetic drugs has now become so widespread that physicians often become unaware of the fact that various problems still remain unsolved in connection with the proper development of chemotherapy. The experiments so far carried out with laboratory animals or with human beings clearly show that these drugs are mainly bacteriostatic, i.e., they

mainly inhibit the multiplications of the micro-organisms in the body. It is the usual natural body defences that really kill the bacteria. Consequently, the more powerful these defences are the more rapid and complete would be the destruction of the micro-organisms. This suggests a synergy treatment, i.e., a combination of immuno- and chemotherapy. The researches of Fleming (1938), De and Basu (1938), and Loewenthal (1939) with experimental animals revealed the utility of such combined treatment. Cokkinis and McElligott (1938) from their clinical observations in gonococcal infections are of opinion that the treatment with the drug be either delayed for a time to allow the body immunity to develop as a result of the infection, or else the immunity be artificially induced by vaccine therapy. In cases of pneumococcal infections there are various difficulties in following up with the serotherapy (J.A.M.A., 1940) and there is no statistical record still in evidence showing the efficacy of a combined treatment of serum and sulphapyridine (the anti-pneumococcal drug) (Finland *et al.*, 1939). Fleming (1939), however, suggests that in such infections a combination of polyvalent vaccines and sulphapyridine would afford a better result (Maclean *et al.*, 1939). That the synergy treatment with specific serum and sulphanilamide is a more useful and effective means of combating pneumococcus type III pneumonia has again been advanced by Finland and Brown (1939).

Conclusion

Considering the various aspects of this new therapy in combating bacterial diseases it seems that in streptococcal, meningococcal and urinary infections the less toxic and cheaper product sulphanilamide should be the usual drug of choice. But for various trade names it is often difficult for a physician to trace the true nature of a product. It may be said here that Prontosil Album (Bayer), Sulphanilamide-p (British Drug House and Burroughs Wellcome), Bisulphonamide (Bengal Immunity), Streptocide (Evans), Septanilam (Glaxo), and Bactesid (Continental Drug) are all products containing pure p-amino-benzene sulphonamide (sulphanilamide). In gonococcal infections sulphanilacetamide is a better tolerated drug. Albucid (Schering) as well as Bianicide (Bengal Immunity) contains this compound. Sulphapyridine is the only potent drug until now discovered against true pneumococcal pneumonia. M.&B. 693 (May and Baker) is the proprietary product containing this chemical. There is also Sulphapyridine (Merck Co., U.S.A.). If the infection be of type III, it may be more safely treated by sulphanilamide combined with sera or vaccine. This synergy treatment is also found to be more beneficial in gonococcal infections. Whenever a parenteral mode of administration is found necessary, the phenyl-propyl-amino sulphanilamide disodium sulphonate (VIII) might be

more freely used. Soluseptasine (May and Baker), or Bisulphonamide injection (Bengal Immunity) contains this product. In pneumococcal infections the sodium salt of sulphapyridine is again available for injection. Whatever product is used, it must be from a stock properly prepared, stored and standardized. In the case of tablets, the question of time of disintegration, and, in the case of solution, its storage away from the light are of special importance (De and Basu, 1937).

When one drug is found ineffective, the other may be used, or, when one mode of treatment fails, the other method should be followed. It must be remembered that the conjugation by acetylation in the system renders the drug ineffective. The degree of conjugation varies with individuals and this is why the precise therapeutic effectiveness cannot be always predicted. The effectiveness of any drug in human medication depends upon the systemic condition of the particular patient in question. Finally, it is to be noted that any therapy has its limitations, as well as its dangers. A correct and proper method of treatment, therefore, demands constant observation by a careful physician.

ERYTHEMA STANDARD FOR DOSE IN LIGHT THERAPY

By P. M. MEHTA, M.D., M.S., F.C.P.S.
Director, Solarium, Jamnagar

THE administration of medicine to the patient is the easiest part of the system of biochemical medicine. Measurements are the necessary foundation of any science or art. Measurement which is very easy in the case of drugs is a very complicated process in case of radiations. This circumstance is due largely to the usually inconstant nature of the source of light and to the marked variation in response that different individuals and their tissues show to irradiation. The response is different in the aged and the young, in the fair and in the dark, in males and females, in people living outdoor and indoor lives, in different seasons, and a difference is even noticed in the various regions of the same person.

The solar radiations are not yet fully understood. What we know is only an infinitesimal part of the solar spectrum. Even in this small portion we have not been able to separate each individual radiation. We know groups of rays, but not the individual rays which compose the group. Similarly with regard to the rays which spread over the vast range of the electromagnetic spectrum and which number millions and whose wave-length ranges from .0004 Å to many kilometres. Therefore when we speak of the ultra-violet rays or x-rays, we do not

particularize single separate rays with the same clear-cut precision, as when we speak of hydrogen we refer to the individual element having the invariable atomic weight of 1. But we refer to groups of rays which come within a particular range of wave-lengths. Now within this range, there are hundreds of different rays with varying wave-lengths. For aught we know their actions may also be varying. We group them relying on rough similarities in their effects.

Such are the indefinite materials with which the radio-therapist has to work. Even these, such as they are, are materially affected by reflection, refraction, and atmospheric absorption during transmission. The radiations pursue a straight course in ether, but as soon as they come into contact with the earth's atmosphere their course is affected by its material contents. Where the atmosphere is thickly laden with dust particles, as over big cities, the short wave-length radiations are almost entirely absorbed. This is with regard to the sun's radiations. The quality of radiations produced by artificial methods varies according to the source of production and also at different times from the same source; the distance is also an important factor to be considered, as the intensity of radiation varies inversely with the square of the distance. Moreover, the organ of the body through which the radiations pass behaves in different manner in different individuals. The skin of one man may allow a certain amount of radiations to pass. The skin of another man may not allow the same quantity to pass. So this will require the dose to be varied in each case. The skin performs various functions, the chief of them being protective, sensory, heat-regulating, respiratory, secretory, and excretory. To the radio-therapist the heat-regulating and protective functions of the skin are of great importance in determining the dose. Skin is a rough rampart protecting the body from all harmful contacts—chemical or physical. It is in fact an expansion of the nervous system. Skin has a network of sensory nerve terminals which are sensitive to the slightest touch or irritation. If the attacking irritant is mild the skin remains unaffected, but if it is a strong one, which is likely to be harmful to the body, there follows a battle royal in our tissues at the site of entrance of the irritant. The blood vessels in the affected spot dilate causing an increase in the blood flow. A condition of hyperæmia follows which is commonly seen in the early stages of inflammation. It begins with redness and develops further stages according to the strength and intensity of the irritant. The exuded leucocytes and serum offer opposition to the intruder. After the enemy is destroyed the inflammation subsides gradually. Where the irritant is a radiation, then too the same result follows. This reaction of the skin to radiations is technically called erythema.

The effect of the sun's rays on the skin

Erythema is a local redness of the skin which develops in 1 to 8 hours depending on the sensitivity of the subject and intensity of radiations. It is a true inflammatory reaction as a result of the stimulus of radiant energy. It is a just hyperæmic stage of inflammation.

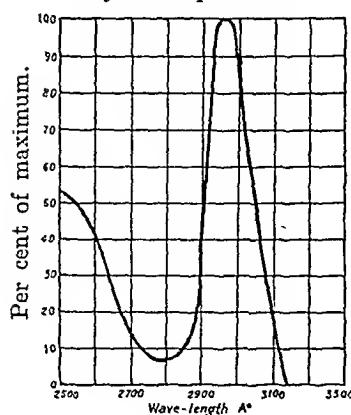

Infra-red rays, light rays and ultra-violet rays are the three kinds of radiations which are used in light therapy. The skin is sensitive to them but in different ways. Infra-red rays form the largest part of sun's radiations. Their proportion is more than 50 per cent. In artificial sources of light too, their proportion is always more than 2/3. The skin is therefore accustomed to heavy doses of infra-red rays. As the effects of infra-red on the skin are immediate and easily detectable by the sensation of heat, the dose in the case of infra-red can be easily determined by the limit of tolerance of the patient. As there are no bad after-effects, there is no harm in taking the dose to the extreme limit. The same may be said about visible light rays. The eyes can easily detect excess of light. There is also a thermal effect and the tolerance level of the skin and the eye is a safe guide for determining its dose. Ultra-violet rays are different from those two in their effects. The body is not accustomed to heavy doses of ultra-violet rays; their percentage in sunlight is only 4. They cause no immediate effects on the body; their effects are seen a few hours after exposure. They produce toxic effects on skin, eyes, etc. Their action is chemical and multifarious. As at the time of exposure, there is absolutely no sensation of any kind, there is every possibility of giving an excessive dose with disastrous effects. A cautious physician might give a small and ineffective dose while an enthusiastic one might cause harm by an excessive dose. We have seen that skin sensibility varies with each individual. It has been known to vary from 1 to 75 times and sometimes even up to 400 times.

The actions of ultra-violet are erythema, pigmentation, vitamin-D activation, bactericidal effect, and effects on blood and metabolism. Erythema and pigmentation are the only effects that can be detected easily by the eye. Pigmentation occurs after a few days, erythema appears after a few hours. Pigmentation requires a bigger dose than erythema. Erythema is produced by the range from 2,400 to 3,200 which is the biologically active range, and so therapeutically most useful range, while pigmentation is produced by a small part of this range from 2,800 to 3,000. Erythema effectiveness is therefore best suited as a test of skin sensitivity.

Erythema response is not produced equally by all wave-lengths between 2,400 and 3,200. The curve rises to its maximum at 2,967 angstroms, descends to minimum at 2,800

angstroms, then rises again to a smaller maximum near 2,500 (*vide chart 1*).

CHART 1
Erythema production.

radiation which can be safely and beneficially administered to the subject. Probably the primary function of the pigment is to arrest the excess of sunlight which has a harmful effect. By absorbing most of the ultra-violet rays which penetrate the horny layer, the pigment protects the blood vessels and the living tissues in the deeper layer of the epidermis from the harmful effects of the sun's rays. This is why we have coloured races in the tropics. White men who expose themselves to the sun of the tropics become bronzed and thus immunize themselves from sun-burn. Dwellers in the arctic snows are pigmented for protection against glare. Pigment protects the underlying structures from an excess of light. It absorbs the visible and ultra-violet radiations and by converting them into heat activates the sweat glands. The sweat in its turn cools by evaporation. The pigment is therefore an indefatigable watchman but indiscriminating. It will not discriminate between beneficial and harmful radiations; it closes the door to all. The dose therefore of the radiations must be so regulated as to be unobstructed by pigment. If deep pigmentation occurs the treatment might become ineffective. The tendency to pigment also varies in different individuals. This will necessitate variations in the dose. The skin sensibility test is therefore of great importance and will remain so till we have devised better and more effective means for fixing the dose. In the present state of our knowledge about radiations, radio-dosimetry must rely on the skin-sensibility test.

Dosimetry

We would have been absolutely at sea in ultra-violet dosimetry if erythema had not come to our aid. When erythema appears on the skin it means that the limit is reached up to which the radiation may be admitted, thus far and no further. Before beginning the treatment the first thing to be determined is the level to which the skin is accustomed and

the level at which it shows resistance or inflammatory reaction in the shape of erythema. The former shows the level above which the dose begins to be effective and the latter gives the level at which it begins to be harmful. So the physician has to operate between these two levels. Erythema thus furnishes a chart, however crude, in an otherwise uncharted sea. By reference to erythema it becomes possible to obtain some numerical precision in ultra-violet therapy. As long as we have no better method of determining the ultra-violet dose, the erythema test is indispensable.

Its usefulness has been recognized since 1906. In Germany, France, England and America many devices were made to carry out the skin-sensibility test. The technique of all these devices was to expose different patches of skin through holes to ultra-violet rays for varying lengths of time. They had many disadvantages. One person had to attend throughout the test to keep the time, and cover and move the holes. The number of holes was insufficient and as they were all of circular shape it became difficult to distinguish them. In 1927 Dr. Saidman invented an automatic instrument which obviated all the disadvantages of the older methods. It has a clock-work device which requires no attention. It is a small instrument. It has 18 orifices of different shapes. When it is set working, an obturator plate begins to move on the holes and covers one hole per minute so that it takes 18 minutes to cover 18 holes. Each succeeding hole remains open for one minute more than its predecessor. The instrument is tied on the body of the patient and is taken off after an exposure of 18 minutes. In the solarium we use Saidman's automatic skin sensitometric test. This sensitometer is firmly applied to the bare skin to be tested, the part, at the predetermined distance at which the subsequent treatment is to be given, is irradiated by the sun or lamp for 18 minutes, and the skin reactions, erythema and pigmentation are noted—

1. Immediately.
2. After a few hours.
3. After a few days.
4. After a month.

The erythema reactions are divided into four degrees—

Erythema of 1st degree	SE ₁ .
" " 2nd "	SE ₂ .
" " 3rd "	SE ₃ .
" " 4th "	SE ₄ .

The pigment reactions are divided into three stages—SP₁, SP₂, SP₃.

First appearance, progress, and evolution of the pigmentation are noted. They are not as useful as erythema in determining the initial dose, as pigment takes a few days to appear, but they are helpful in deciding the increase of subsequent dosage.

The various stages of inflammation

	Naked-eye changes	Microscopic
Erythema of 1st stage.	Light redness. Disappears on pressure.	Epidermic reaction. Dilatation of capillaries and slowing of circulation and increased amounts of blood.
Erythema of 2nd stage.	Light redness. Frank erythema. Granular desquamation. Marked pigmentation follows.	Dermo-epidermic reaction. Stasis of circulation and beginning of exudation of serum and blood cells.
Erythema of 3rd stage.	Intense redness surrounded by bright red areola and slight oedema. Desquamation of large plaques of skin. Pigment marked most in the 2nd week.	Marked exudation of serum and blood cells between layers of skin.
Erythema of 4th stage.	Blister formation surrounded by diffuse redness. Very intense red blister.	Excessive exudation and cleavage between various layers of skin. Necrosis of skin cells.

The fourth stage of erythema is out of the question for general use, except in a very localized area and when required for its caustic action on tissue cells or the destruction of localized infection.

The third stage of erythema also cannot be used for a large area of skin. This exfoliative dose can be made use of only in certain localized infection. The body is afraid of such a concentrated dose of radiation and on recovery from the local inflammatory reaction which will take about a week, it puts on a protecting layer of pigment; thus this area becomes pigmented by the end of 2nd week. This dose is also not desirable for general or constant use.

The 2nd stage of erythema is a stimulative reaction. There is marked stimulation of skin cells causing proliferation and increased activity. Chronic inflammatory condition of the skin may be stimulated to healthier reaction. The blood under the skin is stimulated leading to activation of the leucocytes and vitamin D is produced. The only difficulty is that pigment cells are also stimulated and form a prominent pigment layer in a week's time which obstructs the passage of the radiation subsequently. Moreover, there is some desquamation of skin cells. If the desquamation occurs over the whole body, the skin is not in a fit condition for radiation treatment.

In the first stage of erythema dilatation of the vessels, which is an effect seen in counter-irritation by thermal agents or any kind of mild irritant, physical or chemical, occurs. This comes immediately and disappears with equal rapidity, unless the next stage, stasis, is reached in the vessels. This stage may be caused by infra-red radiations (heat rays), in which case it appears immediately, or it may be caused by ultra-violet rays, in which case it appears after a few hours, in other than a few exceptional conditions. Skin circulation is stimulated, and there is mild stimulation of skin cells, not sufficient to cause proliferation; hence no new pigment layer is formed. So it is possible to make use of this dose daily even for the whole body. No after-effect is left on the skin. There is mild stimulation of skin and its function. Stimulation of the circulation underneath the skin has a soothing effect on the nerve terminals. This dose is desirable when the generalized function of the skin is to be stimulated, or a secondary effect on the general circulation or nervous system is desired.

When general irradiation over the whole body is to be given, the skin test is usually taken on the back. But when local treatment is to be given the skin on the part to be treated is tested or on any other part which has a similar thickness of skin. The skin is not the same thickness all over the body; over the papillæ on the forehead it varies between 0.06 and 0.09 mm., on the cheek between 0.06 and 0.01, and on the neck, arm, abdomen, back and leg between 0.04 and 0.15. Between the papillæ it is thicker. The number of papillæ that cover the entire surface of the body are estimated to be 150,000,000. The dermis in most parts of the body is between 1.7 and 2.4 mm. thick.

The thickness of the skin is also a cause of variability in its sensitivity. As thickness varies in different places in the body, the skin sensitivity also varies in the same body. So not only is there a difference in skin sensitivity of different individuals, but in the same individual it varies from part to part according to variations in thickness. For local treatment therefore the skin of the part to be treated is tested or of another part with similar thickness.

Within 18 minutes the graph of the patient's skin sensibility has been drawn to become visible after a few hours. It is a harmless biological experiment on the patient himself. Eighteen minutes is quite a sufficient time to show the erythema level in 60 per cent of individuals. In 40 per cent the exposure time has to be doubled or even trebled. The graduation of the exposure through 18 equal divisions makes it possible to attain a very high degree of accuracy. Thus Dr. Saidman's invention may be said to have laid the foundation of rational dosage in ultra-violet therapy. It has solved the difficult problem in a very simple and accurate manner. No doctor who gives ultra-violet treatment should be without it. It is

simple and in no way costlier than the routine instruments of diagnosis used in clinical medicine.

The skin-sensibility test neither requires any special study nor involves any heavy expense, and, therefore, there is then no excuse for any physician giving ultra-violet treatment for not making the skin test an essential preliminary to treatment.

While the development of measuring devices and methods and accumulation of knowledge pertaining to biological effects of radiation are progressing the skin-sensibility test, i.e., the production of erythema, has been adopted as a basis of appraisal. Even when adequate knowledge and measurements become available, the erythema basis may remain as the most practical and important guide.

Dosage

Now a few words about the application of erythema value of the skin test in the determination of the initial and subsequent progressive doses of treatment. From the 18 patches on the skin by means of the sensitometer, we must find out the first patch where the skin begins to show a slight tinge of redness. This is the point where the tolerance level is being exceeded. The patch where the redness becomes pronounced is the point where the exposure begins to have harmful effect. The first patch is called SE_1 and the second SE_2 . The dose has to be manipulated between these two landmarks. SE_1 is just above the level to which the body is accustomed. If any therapeutic effect is to be obtained something more than this level must be given. Just as in the case of the habitual opium-eater a larger dose than he is used to is required to bring about the desired result. The safer course is, however, not to begin with SE_1 at once, but a little below it. The treatment is a graduated course and we have to go on accustoming the skin to larger doses. The very reason which makes the skin variously sensitive to ultra-violet makes it possible by gradual increases to raise its tolerance level by 2 to 5 times. The property of the skin to get accustomed to stronger radiations by use has made ray therapy so extensively useful. Both SE_1 and SE_2 can be pushed higher and larger doses can be administered. As ultra-violet rays are present in the majority of light sources and in the solar radiation, it is necessary to take the erythema test before giving any light therapy.

The course of treatment in ray therapy must set forth the dose to begin with, its gradual increase, the intervals at which it is to be given, and the length of time for which the treatment should be continued. Ordinarily the beginning for general irradiation should be made with a dose which is $1/3$ or $1/4$ of SE_1 ; this dose should be gradually increased to reach SE_2 , after five or six exposures. This increment will be about $1/6$ of SE_1 per exposure.

The dose for regional treatment should be one and a half times or twice as much as for general treatment.

The dose for local treatment may be carried to any extent up to SE_2 or SE_4 according to requirements.

Feeble doses should be given to infants with rickets or tetany, to premature babies and to adults suffering from peritoneal or pulmonary tuberculosis, hyperthyroidism, hypersensitive dermatitis, trophic lesions, or thermic instability. The initial dose in such cases should be $1/6$ to $1/8$ of SE_1 , which should be taken to $1/2$ of SE_1 , in about eight or ten sittings.

General treatment may be given once a day. Regional treatment may be given daily, but, as it is stronger, it would be advisable to give it on alternate days. Intense local doses should not be given more than once a week. In the treatment of sensitive patients or sensitive parts such as the larynx or urethra, the interval should be made longer. If as a result of the exposure the patient complains of fatigue or headache, or shows a rise of temperature, nervous excitement, or increased sensitiveness in the part irradiated, the interval must be increased.

In general and regional treatment, the average number of exposures required are twenty to thirty. In cases where prolonged treatment is to be given, it often happens that the patient ceases to show further improvement after two or three months. This is probably due to the skin, as well as the body, becoming accustomed to the radiation. This is seen less in regional treatment than in general treatment, as all the parts are irradiated daily in general treatment, while in regional treatment each region gets its turn of irradiation after a long interval. When this happens, treatment should be stopped for a month after which it may be resumed.

In emergency cases where urgent treatment is to be given, and there is no time to take the test and, generally, where there are no means to take the test, the following general facts may be kept in mind. Sensitiveness of the skin is higher in the following conditions :

1. When the skin is thin, fair, and light-haired.
2. When there is absence of skin pigment, as in albinos.
3. The presence of certain diseases, such as hyperthyroidism, diabetes, syphilis, malaria, and phthisis.
4. Presence of certain drugs or substances in the system, e.g., fluorescent dyes such as trypaflavine, eosine and methylene blue, heavy metals, such as gold, silver, bismuth and arsenic, and certain drugs, e.g., iodine and thyroldin.

Sensitiveness of the skin is diminished in the following conditions :

1. When the skin is thick, dark and thickly haired.
2. When there is excess of pigment in the skin.
3. Presence of certain diseases, such as hypothyroidism, rheumatic conditions, dystrophia adiposogenitalis, etc.

The average dose for general irradiation with ultra-violet is about 1 to 3 minutes and with total sunlight about 5 minutes. The dose for regional irradiation may be 2 to 3 times the dose for general irradiation. These doses should be reduced in cases where there is reason to suspect hypersensitiveness.

The skin test is taken to determine the dose in each case so that the prescription must be written in terms of the erythematous value obtained by means of the test. Erythema of the particular degree is the time taken to produce that degree of erythema in the individual test. $1/2 \text{ SE}_1$ would mean half that time and 2 SE_1 would mean double that time, 3 SE_1 would mean thrice that time and so on. In the case of ultra-violet and total sunlight, the dose must be prescribed in SE_1 terms as shown above. In the case of pure infra-red the prescription may be written in minutes. The prescription

should state the initial dose, the maximum dose, the rate of increase, and interval between exposures.

The skin tests by the skin sensitometers provide an interesting statistical study. Besides being a guide for ultra-violet treatment when taken in the mass, they furnish data for various classifications from different points of the human skin and its behaviour. They might lead to the finding of properties of different kinds of skins. They may furnish clues to general principles of skin sensitivity. Dr. Saidman has published a record of skin tests which he took in the solarium in France. They necessarily relate to skins of European people. During the last five years of the working of our solarium, we have kept detailed records of 3,477 skin tests, a summary of which is published herewith. It is, I believe, the first record of skin tests in the tropics.

TABLE I

Showing mean of SE_2 and SE_3 , and number of patients at different values of SE_1 , for tests taken with STR (solarium total radiation) (vide chart AI)

Relative mean for SE₁ in males and females at different ages.

Conclusions

1. Erythema begins to appear after three hours and takes about 8 hours to develop fully.
2. Pigment begins to appear after a week and fades away gradually after a period of two or three months.

3.

	STR	Arc lamp	Hg. lamp
SE ₁ was seen in	55.5%	65.5%	71.7%
SE ₂ " "	25.5%	34.2%	53.9%
SE ₃ " "	8.7%	2.0%	4.3%
SE ₄ " "	Nil	Nil	Nil
No skin reaction "	44.5%	34.5%	28.3%

4. The skin of tuberculous patients seems to be hypersensitive and that of patients suffering from rheumatism and allied conditions is hyposensitive.

5. The most sensitive age is between 21 and 30 years and the least sensitive between 1 and 10.

6. Accustoming can be carried up to 8 to 10 times if gradually and carefully done.

7.

	STR	Arc lamp	Hg. lamp
The mean of SE ₁ in males	11.9	9.4	7.7
" " SE ₁ " females	12.1	9.0	7.1
" " SE ₁ " male	15.1	15.4	12.5
" " SE ₁ " female children.	12.1	15.2	13.8

In the solarium we get patients mostly from Jamnagar State, which has an area of about 4,000 square miles. The State is between latitudes 22.58°N. on the north and 21.43°N. on the south and between longitudes 69.11°E. on the west and 71.34°E. on the east.

Medical News**THE INDIAN HONOURS LIST**

2ND JANUARY, 1941

THE following are the names of medical men, and others, associated with medical institutions, in the Indian Honours List of date 1st January, 1941. We offer them our congratulations.

K.C.I.E.

Major-General E. W. C. Bradfield, C.I.E., O.B.E., I.M.S., Medical Adviser to the Secretary of State for India, and lately Director-General, Indian Medical Service.

Knighthood

Brevet-Colonel R. N. Chopra, C.I.E., I.M.S. (retired), Professor of Pharmacology and Director, School of Tropical Medicine, Calcutta.

C.S.I.

Major-General H. C. Buckley, K.H.R., I.M.S., lately Surgeon-General with the Government of Bombay.

Variations in sensibility according to sex

The sensitiveness of the skin of adult females is about 10 per cent less than that of the male adults in India, while in France it is the reverse. In the case of children in both the countries, the sensitiveness of female children is higher by 10 per cent.

External appearance of the skin is not a sure guide with regard to its sensibility. A dark skin may sometimes show a higher sensitiveness than fair skin. The skin test therefore should always be resorted to.

The skin sensitometric tests taken on a large scale in the Institutes at Paris, Aix-les-Bains and Jamnagar, have revealed very interesting facts about the skin sensibility of individuals living in two entirely different climatic conditions.

The average time taken to produce various erythema reactions is :—

	France	India
SE ₁	.. 3.5 minutes	7.0 minutes
SE ₂	.. 7.0 "	11.6 "
SE ₃	.. 10.0 "	15.1 "

Indians require at least 50 per cent more ultra-violet than Europeans to produce the same effects.

Variations in sensibility according to age

The following table gives the diminishing order of sensibility in France and India :—

	France	India
Most sensitive age	20-30	16-30
	31-50	31-50
	15-20	11-25
	50-70	50-70
Least sensitive	10-15	6-10
	2-4	

The sensibility is variable in infants under twelve months of age. It is least in the children up to ten and highest at between 16 and 30 years. Variations according to age are similar in both the countries.

C.I.E.

Lieutenant-Colonel H. E. Shortt, I.M.S., Director, King Institute, Guindy, Madras.

Lieutenant-Colonel H. H. Elliot, M.B.E., M.C., I.M.S., Surgeon to His Excellency the Viceroy.

Lieutenant-Colonel D. Clyde, I.M.S., Civil Surgeon, Lucknow.

Lieutenant-Colonel W. H. Crichton, I.M.S., Chief Health Officer, Delhi.

C.B.E.

Ruth Young, M.B.E., Women's Medical Service, lately Principal, Lady Hardinge Medical College, Delhi.

O.B.E.

J. R. Haddow, Indian Veterinary Service, Veterinary Research Officer-in-charge of Serology, Izatnagar.

Lieutenant-Colonel S. N. Hayes, I.M.S., Professor of Midwifery, King Edward Medical College, Lahore, and

Medical Superintendent, Lady Willingdon Hospital, Lahore.

Lieutenant-Colonel G. D. Malhotra, I.M.S., Civil Surgeon, Moradabad.

S. R. Moolgavkar, Esq., Professor of Surgery, Grant Medical College, and Honorary Surgeon, J. J. Hospital, Bombay.

Major M. Taylor, I.M.S., Superintendent, European Mental Hospital, Kanke, Ranchi.

M.B.E.

Dossibai Jehangir Ratenshaw Dadabhoy, Honorary Consulting Surgeon, Cama and Albless Hospitals, Bombay.

Miss Ursula Marie Lobo, Women's Medical Service, Junior Branch, Shegaon, Buldana District, Central Provinces and Berar.

F. Barretto, Assistant Director of Public Health, in charge of the Public Health Laboratory, Poona.

Honorary Captain Rai Bahadur N. N. Dutt, Medical Practitioner, Calcutta.

Major Sayad H. Shah, Punjab Civil Medical Service, Army in India Reserve of Officers, Superintendent, Old Central Jail, Multan.

Assistant Surgeon W. St. Alban Hendricks, Civil Surgeon, Gangtok.

A. J. Noronha, Esq., Lecturer in Bacteriology and Pathology, B. J. Medical School, Poona.

Assistant Surgeon A. J. Selvey, Acting Vice-Consul and Medical Officer, British Consulate General, Kashgar.

R. S. Tirodkar, Esq., Professor of Medicine, Grant Medical College, and Honorary Physician, J. J. Hospital, Bombay.

Kaisar-i-Hind Gold Medal

Miss Reba Cuthbert Hunsberger, Lady Doctor-in-charge, Memorial Hospital for Women and Children, Sialkot City.

Daisy Elizabeth Munro, M.B.E., Lady Superintendent, Civil Hospital, Karachi.

R. G. Cochrane, Medical Superintendent, Lady Willingdon Leper Settlement, Chingleput.

Lieutenant W. P. S. Mitchell, M.B.E., Indian Medical Department, Chief Medical Officer, Bastar State.

Lieutenant-Colonel J. L. D. Yule, Indian Medical Service, lately Officer Commanding, Indian Military Hospital, Delhi Cantonments.

Bar to the Kaisar-i-Hind Gold Medal

Mrs. Olive Monahan, Chief Medical Officer (retired), Kalyani Hospital, Madras.

Kaisar-i-Hind Silver Medal

Robina Margaret Gertrude Brown, General Secretary, Indian Red Cross Society, Bengal Provincial Branch, Calcutta.

Winifred Cole, Rajputana.

Miss Mabel Graham, Matron of the St. Columbus Hospital, Hazaribagh, and Superintendent of the Nurses' Training School attached to the Hospital, Bihar.

Miss Ethel Mary Hadow, Zenana Mission Hospital, Tank, N. W. F. P.

Miss Ada Racine Simmonds, Nursing Sister, Chureh Missionary Society Hospital for Women, Multan Cantonment, Punjab.

Rai Bahadur J. P. Gupta, Provincial Medical Service, Medical Officer-in-charge, Sadar Hospital, Aligarh.

Dr. A. M. Kerr, Medical Officer-in-charge of the Mission Hospital, Jalalpur Jattan, Tehsil and District Gujarat, Punjab.

Dr. V. C. Rambo, Doctor-in-charge, Mungeli Area Christian Hospital, Bilaspur.

The Reverend D. S. Savarkar, Honorary Superintendent and Treasurer, Kondhwa Leper Hospital, Poona.

Dr. S. N. Sen, Private Medical Practitioner, Jamulpur, Honorary Ophthalmic Surgeon to Monghyr Sadar Hospital, Bihar.

Dr. B. K. Sikand, lately Secretary, Tuberculosis Association of India, New Delhi.

Dr. The Reverend C. Wyder, Superintendent, Kothara Leper Asylum, Ellichpur Taluk, Amraoti, Central Provinces and Berar.

Bar to the Kaisar-i-Hind Silver Medal

Lucia Navamanie Veerasinghe Chinnappa, Assistant Directress of Public Health (Maternity and Child Welfare), Madras.

Miss Elizabeth McMaster, Principal Doctor of the Canadian Mission Hospital for Women, Indore.

The Reverend P. A. Penner, Superintendent, Bethesda Leper Home, Champa, Bilaspur District.

Kaisar-i-Hind Bronze Medal

Sister Marie Cecile, Matron, St. Teresa's Hospital for Women, Kurnool, Madras.

Dr. K. W. Advani, Medical Practitioner, Sind.

Dr. N. Angami, Sub-Assistant Surgeon, Kohima, Naga Hills.

Jemadar P. Singhi, Indian Medical Department, Sub-Assistant Surgeon, King George's Royal Indian Military School, Jullundur.

Jemadar Syed R. Ahmad, Sub-Assistant Surgeon, Indian Medical Department, in charge British Consulate Hospital, Zabul, Iran.

Dr. N. B. Sen Gupta, Sub-Assistant Surgeon in charge of the Leper Asylum, Sylhet.

Dr. T. R. Tewari, Punjab Civil Medical Service, Assistant Surgeon, Punjab.

Khan Bahadur

Khan Sahib Shaikh Ghulam Muhammad, Assistant Inspector-General of Civil Hospitals, Punjab.

Khan Sahib Risaldar H. M. Suleman Bahadur, o.b.i., Indian Army Veterinary Corps (retired), Military Veterinary Hospital, Poona.

Rai Bahadur

Rai Sahib S. C. Ghosh, Honorary Surgeon, Medical College Hospitals, Calcutta.

Rai Sahib M. P. Mehray, in charge Khairabad Eye Hospital, Sitapur District.

Dr. R. N. Darbari, Medical Practitioner, Allahabad.

Dr. Lala G. D. Kapur, Clinical Assistant to the Professor of Surgery, King Edward Medical College, Lahore.

Rai Sahib N. Pal, Lecturer in Surgery, Prince of Wales Medical College, Patna.

Rai Sahib S. B. Dutta, Civil Surgeon, Saran, Chapra.

Dr. B. Sen Gupta, Civil Surgeon, Balasore.

Rao Bahadur

Dr. M. J. P. S. Pillai, Medical Superintendent, Barnard Institute of Radiology, Madras.

Dr. A. T. Nayudu, Assistant Director of Public Health, Madras.

Dr. R. A. Kalle, Civil Surgeon, Bijapur, Bombay.

Dr. R. C. Motwani, Professor of Anatomy, Grant Medical College, Bombay.

Dr. B. R. Chandorkar, Civil Surgeon, Bhandra, C. P.

Rao Sahib M. Ramaswamy, Honorary Secretary, Indian Red Cross Society, Bangalore City Branch, Mysore.

Shifa-ul-Mulk

Hakim A. Usmani, Member, Board of Indian Medicine, Allahabad.

Hakim M. H. Khan, Proprietor, Chashma-i-Hayat Pharmacy, Ajmer.

Vaidyaratna

Kaviraj P. Sinha, Superintendent, Ayurvedic College, and Professor of Pharmacy, Hindu University, Benares.

Khan Sahib

S. Zainalabedin, Esq., Civil Assistant Surgeon, Kyaklat, Burma.

A. M. Naqui, Esq., State Surgeon, Barwani State, Central India.

Jemadar M. G. Ali, Indian Medical Department, Sub-Assistant Surgeon, His Excellency the Vicerey's Dispensary.

MEDICAL NEWS

Rai Sahib

Dr. A. B. L. Mathur, Lecturer, Medical College, Agra.

Dr. J. L. Agarwala, Medical Officer-in-charge, Kalyan Eye Hospital, Khatauli, U. P.

Dr. G. Sahay, Assistant to the Civil Surgeon, Patna, Medical Officer-in-charge, Patna Police Hospital, and Lecturer in Medical Jurisprudence, Patna Medical College.

Dr. K. B. Sahay, Teacher of Pathology and Deputy Superintendent, Darbhanga Medical School, Laheria Sarai.

Dr. S. N. Mukharji, Private Medical Practitioner, Deoghar.

Dr. S. N. Malhotra, Chief Medical Officer and Sanitary Commissioner, Karauli State.

Pandit R. R. Shukla, Sub-Assistant Surgeon, Medical Department, Ajmer-Merwara.

Dr. A. B. Sen, Assistant Surgeon, A. B. Railway, Chittagong.

Rao Sahib

Dr. D. R. Annamalai, Civil Assistant Surgeon, King Institute, Guindy.

Dr. A. Y. Deshpande, Ellichpur, Amravati District, C. P.

Dr. T. H. Trivedi, Pathologist, West Hospital, Rajkot Civil Station, Western India States Agency.

Dr. M. N. Vijaykar, Medical Superintendent, Antop Village, Port Trust, Bombay.

TUBERCULOSIS WORKERS' CONFERENCE

THIS year, as last year, the value of the conference was proved, not only by the papers read and the discussions which followed, but perhaps even more by the personal intercourse between the members coming from all parts of India, by the opportunity for sharing individual problems, and by the inspiration of the growing feeling that they were all banded together in one brotherhood in the campaign against tuberculosis in this country.

SUMMARY OF PAPERS AND DISCUSSIONS

'The Progress of the Tuberculosis Association's Campaign against Tuberculosis in India' by Lieut-General G. G. Jolly

The paper summarized briefly the present stage in the campaign against tuberculosis in India, from the point of view of the central association, since February 1939, the date of the inauguration of the association. The establishing of contacts with provincial and state committees, with government and local authorities and with tuberculosis workers, was one of the first steps. General Jolly paid a tribute to the help of Lady Linlithgow in this respect. The tours of the medical commissioner had also been of the utmost value. Thirteen provincial and eleven state associations were now affiliated to the centre, and several more associations were in process of formation. There had been a rapid growth of tuberculosis institutions, but there was so far a lack of after-care. Of the two institutions to be run by the centre, the model clinic in New Delhi was complete, and the Kasauli sanatorium was being begun. Short courses of post-graduate training in tuberculosis for general practitioners had been held in Bombay, Calcutta and Madras; Madras had also begun a 5 months' diploma course in tuberculosis. The paper also touched on the training of tuberculosis health visitors, tuberculosis propaganda and the need of a good India tuberculosis film, and tuberculosis surveys. Organized home treatment had been suggested by the central committee as a policy practicable at the present stage of the development of the campaign treatment and in this the general practitioner had a prominent place.

Discussion

This ranged over a large number of subjects connected with various aspects of tuberculosis work in India. Foremost in the discussion was the place of private practitioners in the tuberculosis campaign; their co-operation was absolutely essential, but in order that this

co-operation might be obtained it was necessary that doctors in charge of clinics should not be allowed private practice; the system of staffing clinics with honorary doctors was impracticable; the non-co-operation of private practitioners was in some case due to fear of losing their patients.

Another subject discussed was the necessity of co-operation between the public health department and tuberculosis workers, specially as improvement of housing and living standards had to have a place in the tuberculosis campaign.

The place of the central association also came up for discussion, specially as regards the help that it could afford in such work as the planning and advising about surveys, and the allotting of research to different institutions to avoid overlapping and duplication specially when funds were very limited.

Other subjects which found a place in the discussion were the training of tuberculosis workers, doctors and health visitors, and of medical students in tuberculosis; the question of what to do with soldiers discharged from the army as tuberculous; the need of after-care establishments; mobile instead of fixed dispensaries in some areas; the provision of isolation for the poor in organized home treatment.

Several speakers dealt with legislation as regards notification with a view to checking spread of infection, but some thought this too early at the present stage of the campaign in India.

Tuberculosis Surveys

(a) Paper by Dr. R. B. Lal

The tuberculosis survey is an investigation into the social and other factors determining the peculiar distributions of the disease in the community and their trends and also into the potential forces which aid or combat the dissemination of the disease and determine its types. Only on the basis of the results of a survey so defined can a campaign best suited to the community be devised in a rational manner. The paper then dealt with some of the general principles in the methods of approach in pursuit of the objects of a survey and some of the general principles of practical importance in the planning and execution of survey so necessary if the effort of the survey is not to be largely wasted.

(b) Paper by Dr. P. V. Benjamin

The main purpose of tuberculosis surveys is the gathering of knowledge which can be used for the prevention of the disease. In the process of a complete survey there are several stages which are: type I survey for ascertaining the distribution of tuberculous infection in a particular community or area; type II survey including also extent of morbidity and mortality, extent of contact infection and the forms and types of disease; type III survey for investigating the factors which influence infection, morbidity and mortality. Each of these surveys was described and illustrated from such surveys made in S. India by the speaker and his colleagues. He then summed up the experiences and lessons gained from these surveys; definite knowledge about tuberculosis in these areas had been acquired and this could be used for gaining public co-operation in the campaign; the well-to-do are infected as much as the poor; except in a type I survey, a clinic is necessary for taking care of detected cases and thereby helping to sustain public interest and co-operation; a survey must be made to search for infective cases not coming to a clinic; for some for whom home treatment is impossible, a simple form of isolation will be necessary outside the home.

Discussion

There was stressed the necessity of surveys being carried out by well-trained workers, the type of test to be used—von Pirquet or Mantoux—the comparative value of fluoroscopy and radiography and the use of miniature films in surveys, the need for surveys being based on well-established institutions, and the need for help from the central association in advising, planning and assessing surveys, were all brought out in the discussion.

The second day of the conference was taken up with the subject of the influence of environmental factors on tuberculosis.

'The Influence on the Incidence of Tuberculosis by By-laws concerning Buildings, Town Planning, Slum Clearance and Lodging Houses' by Lala Shri Ram, Vice-chairman of the Tuberculosis Association

Municipalities when first constituted had to face only a few simple problems, such as providing a water-supply, lighting and indispensable sanitary services, but now they were faced with the great responsibility of safeguarding and improving public health in their areas. Housing conditions had to be regulated; new buildings could be regulated by building by-laws, but old buildings could only be dealt with by a town improvement scheme. Even where building regulations existed, a popularly elected body often found great difficulty in enforcing them and contraventions were frequently condoned. The town councils should lay down the policy, and the executive staff should then be held responsible for any breaches that occurred. The financing of improvement schemes to open up slums and remove sources of infection was not easy. Under the scheduled tax rules, municipalities had been allotted a few specific items of taxation when the needs were few and primitive, but a revision of tax allocation was now necessary. Town improvement schemes and the developing of a civic conscience by propaganda would all help in the reduction of tuberculosis.

'The Influence of Environment on the Incidence of Tuberculosis' by Lieut.-Colonel E. Cotter

The general features of the epidemiology of tuberculosis have long been known and the factors influencing its incidence can be summed up under nutrition, housing and education. After illustrating the influence of these three factors mainly from investigations in Europe, the paper went on to deal with some constructive suggestions as to what could be done in India. As regards nutrition, the results of researches under the Indian Research Fund Association had now to be applied to the general population by provincial and state authorities in which agricultural and health authorities co-operate. As regards housing, cities, small towns and villages had their different problems; the Delhi improvement trust scheme financed by the proceeds of the entertainment tax was a good example of what could be done in a city; a simpler plan was required in rural areas, the Nazafgarh scheme being an example of this. As regards education, it was hoped that the report of a special committee on health education in schools under the Central Advisory Board on Health, would be of value when it is published.

Discussion

A full discussion followed in which not only tuberculosis workers took part but also representatives of public health departments, municipalities, the army and railways. A full description of the Delhi improvement trust scheme was given by the chairman of the trust. Among the points brought out in the discussion were: the necessity not just for slum clearance, but for re-housing those removed from the slums; the problems caused by the drift of population from the country to the town; the main danger is the infectious case plus local overcrowding and therefore case-finding cannot be neglected; the need for a much wider co-operation between public health, medical and educational departments; education needed for both provincial and local authorities in matters concerned with the spread of tuberculosis; the need for health officers to have power with regard to sanctioning new buildings. The neglect of housing for domestic servants, the influence of purdah, that overcrowding is not always associated with poverty, were also mentioned.

General Jolly, in summing up the day's discussion, said it had been exceedingly productive and exceedingly interesting. The improvement trust system was not new, but the application of a luxury tax to pay for housing the poor was a new idea. Enforcement of

by-laws was a crucial point and to ensure this a scheme similar to that in Burma was suggested in which—

- (1) There was security of tenure for the health officer.
- (2) Local authorities had responsibilities and not merely powers to make by-laws for buildings, which had to be submitted to the local government, i.e., the passing of acceptable by-laws was mandatory, not permissive.
- (3) It was the duty of the health officer to enforce the by-laws dealing with public health passed by the municipality.

The remaining day and a half of the conference were occupied with technical papers.

'Classification of Pulmonary Tuberculosis on Admission and Discharge' by Dr. C. Frimodt-Möller

In a very brief paper the report of the sub-committee on the classification of pulmonary tuberculosis appointed by the Tuberculosis Association was introduced and was further explained by Dr. P. V. Benjamin.

Discussion

Suggestions were made for a system of marks for different criteria taken in assessing stages, but the difficulties of doing this in the present stage of our knowledge and in the present stage of tuberculosis work in India, were brought out. The question whether the pathological type of the lesion should be taken into consideration as well as the anatomical extent of the disease was discussed. The necessity of x-ray examination for a satisfactory classification was well emphasized. In 'discharge' results there was discussion about the classifications of 'arrested', 'much improved' and 'improved', and an additional classification of 'quiescent' was suggested.

'Haemoptysis' by Dr. K. Vasudeva Rao

After stating that in a series of 3,082 cases treated in Madras, 38.6 per cent had haemoptysis of which only 9.4 per cent were severe, the paper dealt with the causation of haemoptysis, the classification of haemoptysis, the time of onset, seasonal variations, epidemic form, and age and sex influence. Prognosis and general management and a review of the methods used to control bleeding, medical and surgical, concluded the paper.

Discussion

In a short discussion the comparative rarity of deaths from haemoptysis was mentioned by some speakers. A doubt was expressed as to the value of the many drugs advocated for haemoptysis. Seasonal variation had also been noted by several.

'Interpretation of X-ray Films in Pulmonary Tuberculosis' by Dr. A. C. Ukil

The paper emphasized the necessity for proper exposure and developing of x-ray films if a reliable interpretation is to be made. In examining a film the following points had to be borne in mind:—

- (1) The general appearance of tissues and organs in the thorax.
- (2) The localization of the shadows.
- (3) The character of the shadows, both in general and from the point of view of tuberculosis.
- (4) The character of striation in the lung fields.
- (5) Deficiency of the normal shadow and its localization and character.
- (6) Differential diagnosis.

After the paper a number of x-ray films were demonstrated to illustrate the paper.

'Tuberculosis and Diabetes' by Dr. R. B. Billimoria

The paper dealt with the pathology of tuberculosis associated with diabetes and gave a short outline of the treatment to be adopted both for the diabetes and the tuberculosis, treatment of both being equally important.

'Intestinal Tuberculosis in its Medical Aspects' by Dr. R. Viswanathan

The paper began with a statement of the frequency of intestinal tuberculosis as a complication of pulmonary

tuberculosis seen at Vizagapatam and then dealt with the pathological anatomy of the condition and reviewed the treatments advocated. Some pathological specimens and lantern slides were shown at the end of the paper.

'Abdominal Tuberculosis in its Surgical Aspects' by Lieut.-Colonel F. J. Anderson

The speaker considered not only intestinal tuberculosis but also other forms of abdominal tuberculosis and spoke of the types of operation he had found of benefit.

Discussion

There was a difference of opinion as to whether intestinal tuberculosis was to be treated primarily medically or surgically, but probably no clear-cut division could be made and some cases must be treated surgically and some benefited best by medical treatment. Some speakers dealt with treatment by pneumo-peritoneum with or without a preliminary incision through the abdominal wall. The frequency of intestinal tuberculosis was commented on by several, both as a primary and a secondary manifestation. The difficulty of differential diagnosis was also mentioned and caution in the interpretation of x-ray films after barium meal was urged.

This year the conference was noted for the keenness and high level of the discussions which followed the papers, and the large number of speakers who took part.

Resolution passed by the committee of experts appointed by The Tuberculosis Association of India in regard to general conditions which should govern the selection of sites for tuberculosis clinics

(1) 'What considerations should govern the selection of sites for tuberculosis clinics?'

The site for a tuberculosis clinic should be selected with a view to its being of the greatest help to the population which it is intended to serve. This will be in, or as close as possible to, the most thickly populated area of the locality.

(2) 'Is it necessary to require any conditions to be satisfied by sites in or near populated areas in respect of either distance from inhabited houses or any other matter as a precaution against the spread of infection?'

No conditions need be laid down with regard to the distance of a clinic from inhabited houses in or near a populated area if the clinic is properly conducted. If a section of a building which is used for other purposes is selected for a clinic, the clinic should have its own separate entrance.

THE INDIAN CHEMICAL MANUFACTURERS' ASSOCIATION, CALCUTTA

THE necessity of according to the manufacturers of chemical and pharmaceutical products the facility to have a clinical trial of their products in the hospitals under the control of Government and local bodies, has been stressed in the course of a communication addressed by the Indian Chemical Manufacturers' Association to all the provincial Governments and major Indian States. It is pointed out that this facility is available in foreign countries and it has helped to obtain for the products manufactured in those countries the proper markets, whereas the absence of this facility in India forms one of the greatest handicaps to the industry. Recently the Medical Research Association in the U.K. in conjunction with Government departments and the Association of British Manufacturers arranged clinical trials of several important synthetic remedies previously obtained from abroad but now being manufactured in Great Britain, in order to ensure that these drugs of British manufacture were equivalent to the corresponding imported products. The Chemical Association states

that several drugs and proprietary remedies identical to those coming from Germany and other foreign countries are now being manufactured in India and the manufacturers are in a position to prepare many more also, but the absence of the facility of clinical test makes it difficult to convince the medical profession and the buyers about the products of Indian manufacture being equally as efficacious as the corresponding foreign medicines, which are looked upon as standard. The facility of clinical trial in India would make it possible for many foreign medicines to be replaced by indigenous ones thus helping the chemical and pharmaceutical industry in this country.

THE INDIAN CHEMICAL MANUFACTURERS' ASSOCIATION, CALCUTTA

As a result of the efforts of the Indian Chemical Manufacturers' Association, Calcutta, the Government of India have decided to exempt benzol used in the manufacture of medicinal preparations from excise duty. The Government of India levied an excise duty of As. 10 per gallon (subsequently increased to As. 12) on benzol on the ground that it can be used as motor spirit as a substitute for petrol. The Indian Chemical Manufacturers' Association had pointed out to the Government that benzol was used as a solvent in the manufacture of alkaloid preparations but on account of the excise duty the alkaloids prepared in India could not stand in competition with the imported alkaloids in normal times. The step now taken by the Government of India would enable utilization of a large quantity of benzol manufactured in coke oven plants which was till now going to waste. It would also give an impetus to the manufacture of alkaloid preparations in this country.

ABSTRACT OF THE MINUTES OF THE BENGAL COUNCIL OF MEDICAL REGISTRATION, DATED 16TH FEBRUARY, 1940

1. The Council had at their meeting of 8th August, 1939, adopted a resolution that it was desirable that the country of qualification, particularly when the qualification had been obtained from a foreign country, should be mentioned along with the abbreviation used for medical degrees, so that the public might not be misled; and expressed hope that a convention would be gradually established by registered medical practitioners, if they followed this practice.

The question whether this should be included in the Penal and Ethical Rules was considered at the meeting of 16th February, 1940: and it was decided that though desirable this could not or need not be included in these rules.

2. On a reference made to the Council on the question as to the propriety or otherwise of supplying personal history of patients in a hospital, such as one for tuberculosis, to life insurance companies, the Council observed that Rule 19 in Part III of the Council's Penal and Ethical Rules was clear enough on the subject and that it would not be proper for the authorities of such hospital to supply personal history of patients treated therein to such companies. The rule is as below:—

'A medical practitioner is under an obligation to his patient to preserve his secrets and in legal matters should, except with the patient's consent, answer questions only at the express direction of the Judge or Magistrate presiding in a court of law. A medical practitioner is not bound to answer questions put to him by policemen except as provided in section 44 of the Criminal Procedure Code.'

3. The Council noticed with regret that an amendment of the Bengal Medical Act, on the lines suggested by the Council from time to time, had not yet been taken up by the Government. They also desired to impress upon Government the necessity of improving the standard of Licentiatehip course, by raising the

preliminary qualification to I.Sc., and extending the period from 4 years to 5 years.

4. The Council also resolved that the departments of the Government of India such as the posts and telegraphs, income-tax, etc., should be requested to follow the Government of Bengal Circular No. 2556 dated the 8th September, 1921, which lays down that when a medical certificate has been given to a non-gazetted officer by a registered practitioner, no further examination by the civil surgeon or a higher medical officer should be required unless the genuineness or veracity of the certificate was doubted.

ABSTRACT OF THE MINUTES OF THE BENGAL COUNCIL OF MEDICAL REGISTRATION, DATED THE 13TH AUGUST, 1940

1. The Council repeated their recommendation that with a view to restraining quack practice, all dispensaries should be licensed and no dispensary should dispense any preparation which is not signed by a practitioner possessing registrable qualification.

2. The Council repeated their recommendation for suitable measures forbidding the use of the prefix 'Dr.' as a medical qualification except by persons possessing registrable qualifications.

3. On the question of propriety of registered practitioners being directors of firms manufacturing medicines, the Council adopted the following resolution:—

'That this Council would not object to the mere association of medical practitioners with firms of manufacturing medicines, whether as directors or shareholders, but the names of such medical practitioners should not appear in any publication (such as catalogue of prices or advertisements) circulated to the general public by the firm or its agents.'

4. The Council amended their Ethical Rule 8 as follows:—

'When a medical practitioner is asked to see and report on a case of illness or injury of a person who is under the care of another registered practitioner or about whom the latter has already given a medical certificate, the former should in all cases give the latter an opportunity to be present at the time of examination, if he so liked: and for this purpose he should direct the patient to inform the latter practitioner in sufficient time.'

The medical practitioner when so seeing or reporting on a case, shall not interfere with the treatment nor make any disparaging remarks about the first diagnosis and treatment, even though he might differ.'

5. Certain cases of medical certificates being given by practitioners without sufficient care were reported and the practitioners were warned by the Council.

6. On the question of registered practitioners teaching medical subjects in Ayurvedic institutions, the following resolution was adopted qualifying section 3, Part I of the Ethical Rules:—

'This section does not apply so as to restrict the teaching of pre-clinical subjects such as anatomy and physiology by registered practitioners, in institutions recognized by the Ayurvedic State Medical Faculty of Bengal.'

7. The Council decided to add a chapter at the end of the *Annual Medical List* giving a list for the general information of all practitioners showing references to various provisions in the law which impose certain legal obligations on them and penalties for default.

APPENDIX TO THE PROCEEDINGS OF THE PENAL AND ETHICAL CASES COMMITTEE, DATED THE 22ND JULY, 1940

(ITEM 5). PART IV

Some legal matters of general information for medical practitioners

1. Calcutta Municipal Act, 1923 (as amended)

Section 435: Every medical practitioner who, in the course of his practice, becomes cognizant of the existence of any dangerous disease in any private or public dwelling-house, other than a public hospital, shall give

information of the same with the least practicable delay to the health officer in such form and with such details as the health officer may, from time to time, require.

'Dangerous disease' means—

- (a) cholera, plague, smallpox, cerebro-spinal meningitis and diphtheria; and
- (b) any other epidemic, endemic or infectious disease which the local government may, by notification in the *Calcutta Gazette*, declare to be a dangerous disease for the purpose of this Act.

Penalty for default, fine Rs. 50

Section 453: Any medical practitioner in attendance during the last illness of any person dying in Calcutta shall, within three days of his becoming cognizant in the course of such attendance of the death of such person, send a written notice to the health officer, as nearly as may be in the form prescribed in Schedule XXII, stating, to the best of his judgment, the cause of death.

Penalty for default, fine Rs. 50

2. Bengal Municipal Act, 1932

Section 377: A medical practitioner or a person practising the medical profession, and in the course of such practice becoming cognizant of the existence of any dangerous disease in any building other than a public hospital . . . shall give true and correct information to such officer as the commissioner may direct, respecting the existence of such disease.

Penalty for default, fine Rs. 50

Section 447: Whenever a birth or death occurs in any hospital within the limits of any municipality in respect of which the local government has directed that all births and deaths shall be registered under the Bengal Births and Deaths Registration Act, 1873, it shall be the duty of the medical officer in charge of such hospital forthwith to send a notice in writing of the occurrence of such birth or death to the commissioners in such form as the local government may prescribe, and in such case no other person shall be required to give information of such birth or death to a registrar under the said Act or to a sub-registrar under this Act.

Penalty for default, fine Rs. 50

3. Bengal Vaccination Act, 1880

Section 5: If any . . . medical practitioner shall be of opinion that any child is not in a fit state to be vaccinated, he shall forthwith deliver to the parent or guardian of such a certificate under his hand according to the form of Schedule A hereto annexed or to the like effect, that the child is then in a state unfit for vaccination.

Section 6: If any . . . medical practitioner finds—

- (a) that a child brought for vaccination has already had smallpox, or
 - (b) that a child who has been three times unsuccessfully vaccinated is insusceptible of successful vaccination,
- he shall deliver to the parent or guardian of such child a certificate under his hand, according to the form in Schedule B hereto annexed, or to the like effect.

Penalty for not giving certificate Rs. 50; for giving false certificate, up to 6 months' imprisonment and fine Rs. 100 (section 28)

4. Dangerous Drugs Act, 1920

A medical practitioner possessing or selling medicinal opium or of any preparation containing morphine, diacetyl-morphine, or cocaine, in contravention of the Government rules prescribing the limits.

Penalty up to 2 years' imprisonment and fine

5. Poisons Act, 1919

Contravening the Rules under the Poisons Act.

Penalty up to 3 months' imprisonment and fine Rs. 500

FEB., 1941]

CURRENT TOPICS

6. Bengal Excise Act

Section 18: Possession of any intoxicant which has not been obtained from a licensed vendor.
['Intoxicant' means the leaves, small stalks and flowering tops of Indian hemp plant (*Caralis sativa* L.) including *bhang*, *siddhi* or *ganja*; *charas*: any mixture with or without neutral materials, if any of the above forms of intoxicating drug or drink made therefrom; and any other intoxicating or narcotic substance or any fermenting against which the provincial Government may specify as 'intoxicant'.]

Penalty up to 6 months' imprisonment and fine Rs. 1,000

Section 53: If any chemist, druggist, apothecary or keepers of a dispensary allows any intoxicant which has not been *bona fide* medicated for medicinal purposes, to be consumed in his business premises by any person not employed in his business.

Penalty up to 3 months' imprisonment and fine up to Rs. 1,000

7. Indian Port Health Rules, 1938 (Under the Indian Ports Acts, 1908)

Rule 8: 'Every medical practitioner, who becomes cognizant that any passenger on board or any member of the crew or any person employed on board any vessel in the port is suffering from any of the diseases specified in rule 3, shall immediately give notice thereof by telephone and in writing to the Health Officer.'

(The diseases specified in rule 3 are plague, cholera, yellow fever, typhus, smallpox, chickenpox, cerebro-spinal meningitis, diphtheria, relapsing fever, jigger, and influenzal pneumonia.)

Penalty for omission, fine up to Rs. 1,000 [section 6(3)]

8. Indian Penal Code

Section 269: Whoever unlawfully or negligently does any act which is, and which he knows or has reason to believe to be likely to spread the infection of any disease dangerous to life.

Punishment up to 6 months' imprisonment and fine
Section 274: Adulteration of drug or medicinal preparation.

Penalty up to 6 months' imprisonment and fine Rs. 1,000

Section 275: Selling or offering for sale the same.

Penalty up to 6 months' imprisonment and fine Rs. 2,000

Section 276: Whoever knowingly sells or offers or exposes for sale or issue from a dispensary for medicinal purpose any drug or medicinal preparation, as a different drug or medicinal preparation.

Penalty up to 6 months' imprisonment and fine Rs. 1,000

Section 284: Whoever does, with any poisonous substance, any act in a manner so rash or negligent as to endanger human life, or to be likely to cause hurt or injury to any person; or knowingly or negligently omits to take such order with any poisonous substance in his possession as is sufficient to guard against probable danger to human life for such poisonous substance.

Penalty up to 6 months' imprisonment and fine Rs. 1,000

INDIAN JOURNAL OF OPHTHALMOLOGY

We have now received the second number of this journal. There was room for a specialist journal on this subject in India and we welcome its publication.

The articles are interesting, particularly one long historical paper on cataract.

The format of the journal is good, and the proof reading has obviously been done carefully; however most of the references are not given in a traceable form, the year only being mentioned in some cases.

We wish the journal the success that the enterprise of its promoters deserves.

Current Topics

Antiseptic Analgesic Tannic-Acid Jelly for Burns

By J. F. HEGGIE
and

R. M. HEGGIE

(From the *Lancet*, Vol. II, 28th September, 1940,
p. 391)

WHEN we were considering the use of an antiseptic tannic-acid jelly for burns in H. M. ships, in which bottles of tannic-acid solution might readily be broken in action at dressing-stations, Prof. W. C. Wilson of Aberdeen told us that he had prepared for him in the dispensary at Edinburgh Royal Infirmary a jelly consisting of acriflavine 0.1 per cent and tannic acid 20 per cent with a glycerine-tragacanth base.

We prepared a similar jelly with proflavine sulphate 0.1 per cent, and, having regard to the use of Nikalgin for burns in the last war, we considered the addition of an analgesic. Tannic acid precipitates alkaloids from solution, but its effect in a jelly was considered to be less rapid; so quinine and urea hydrochloride 0.5 per cent were added. Slow precipitation took place, and chlorbutol 2 per cent and procaine 2 per cent were substituted in separate preparations. Chlorbutol gave very little relief. Procaine gave relief lasting about an hour and has been used more frequently.

Since in the great majority of infected burns reaching this hospital the predominating organism was *Staphylococcus pyogenes aureus*, the jelly was also

made up with methyl violet 0.1 per cent instead of proflavine sulphate. Our observations on the organisms normally present on the skin of naval ratings have proved that pyogenic staphylococci are commonly found.

The formula for the jelly is as follows:—

Tannic acid ..	20.0	per cent.
Proflavine sulphate ..	0.1	"
Procaine ..	2.0	"

in glycerine-tragacanth base.

Methyl violet may be substituted for proflavine sulphate. The glycerine-tragacanth base consists of:

Pulv. tragacanthæ co.	2.0	per cent.
Glycerine ..	10.0	"
Distilled water ..	ad 100	"

The preparation is put up in collapsible tubes or, in hospital, stored in wide-necked well-stoppered bottles.

APPLICATION

On unbroken skin.—When the skin is erythematous and blisters have formed, the jelly is smeared fairly liberally over the affected area and well over the margin on to healthy skin. Two thicknesses of gauze are then applied intimately, another two are added, and with a thickness of wool the whole is bandaged and left for about a week. This was the routine adopted in the cases we have treated personally.

On the removal of the dressing at the end of a week the consistence of the jelly had altered according to

the amount of evaporation and varied from that of an unguent to peeling flakes. Practically no damage was done to the tissues on removal of the gauze, which came away easily. In areas over which blisters had formed the hygroscopic action of the glycerine had caused the blister fluid to be withdrawn into the dressing; the wrinkled superficial epithelium covered the area. The surrounding skin was slightly dyed. None of these burns became infected.

On broken skin.—The jelly was applied in the same way as for unbroken skin. Where the blisters had ruptured a good tan-coagulum formed. This was separated at the end of ten to fourteen days, and the skin beneath, though thin, was soundly healed. The gauze incorporated in the coagulum facilitated its removal. None of these burns became infected. The tanned area, however, wherever joints were not involved, formed a continuous sheet; consequently there were no cracks. In two cases the burns affected the extensor and flexor aspects of the wrist. In these two cases no wool was used over the gauze dressings. The jelly dried fairly quickly, a good coagulum formed, and cracks developed. A slight amount of purulent exudate was noted, two days later, at the edges of the cracked tan. The patient, who complained of sore-throat, was observed on occasion to use his hand and wrist to shield his mouth on coughing. Bacteriological examination showed staphylococci (coagulase and

haemolysin-positive) present in the fauces and in the exudate from the wrist.

On fingers and hands.—Owing to the constricting effect of the tan on burns encircling fingers and hands completely, the tannic-acid jelly has not been used on such parts. Instead we recommend the use of a jelly of the following composition:

Gentian or methyl violet 1.0 per cent.
Quinine and urea hydrochloride 0.5
in glycerine-tragacanth base
(put up in collapsible tubes).

We have not yet had an opportunity of using this jelly, but gentian violet has been used by others as an antiseptic and coagulating agent in burns.

COMMENT

This tannic-acid jelly appears to have several advantages. Apart from its antiseptic and analgesic qualities, the hygroscopic action of the glycerine in withdrawing the blister fluid is beneficial in making resorption of this fluid impossible. Bacterial growth is diminished by this action of the glycerine and by increased penetration and concentration of the antiseptic dye.

We are trying to obtain a jelly which will make for equal ease in dressing and produce a pliable softer incrustation rather than the rigid tannic-acid eschar.

Reviews

A GUIDE TO HUMAN PARASITOLOGY FOR MEDICAL PRACTITIONERS.—By D. B. Blackstock, M.D. (Edin.), D.P.H. (Lond.), D.T.M. (Liverpool), and T. Southwell, D.Sc., Ph.D., A.R.C.Sc., F.Z.S., F.R.S.E. Fourth Edition. 1940. H. K. Lewis and Company, Limited, London. Pp. viii plus 259, with 122 illustrations and 2 coloured plates. Price, 12s. 6d.

To produce a book of this kind needed courage and could only have been undertaken by men whose reputations are established beyond question as are those of both authors. The authors are, or were, teachers on the staff of the Liverpool School of Tropical Medicine and are used to teaching post-graduate students; they are therefore unlikely to underestimate the capacity of the student to learn this subject. Yet, parasitology has been reduced by them to a much simpler and more practical form than one finds in most textbooks designed for students. The question arises, 'Are the authors right?' or 'Have they overdone the simplification?' We unhesitatingly give the verdict in favour of the authors. We are obviously not alone in our opinion, for this is the fourth edition, one edition having been reprinted, since the book was first published in 1931.

The book is essentially what the title claims for it; it is in no sense a textbook, but a guide. It will help the specialist only in so far as his teaching is concerned, but the practitioner will find in it all he will want to know about the diagnosis of the parasitic infections he is likely to encounter in his daily work, and sufficient about the life cycles of the parasites to enable him to institute preventive measures, when he has an opportunity to do so.

As far as protozoology is concerned, the sixty pages devoted to this will be sufficient for the qualifying and M.B. examinations, but for post-graduate examinations, such as the L.T.M. and D.T.M., a certain amount of supplementation will be necessary. The helminthological portion is however quite sufficient for either of these examinations.

No essential changes have been effected in this fourth edition, and few additions made, as it is not the type of book that becomes out-of-date readily, so that we cannot recommend those who have an earlier edition to buy the book, but we do very strongly recommend

it to those not already familiar with it. Teachers in medical schools and colleges will find the tables and diagrams, which are a prominent feature of the book, invaluable.

A SYMPOSIUM ON THE BLOOD AND BLOOD-FORMING ORGANS.—By various authors. 1939. The University of Wisconsin Press, 811, State Street, Madison, Wisconsin. Pp. viii plus 264. Illustrated. Price, \$3.50

SYMPPOSIA have a way of being very disappointing and the reason is fairly obvious. When an individual writes a paper in a journal, it is usually because he has something he wishes to announce to the world, the results of a laboratory investigation or a series of clinical observations, or a theory he has formulated; he usually does this in his own time on his own initiative. Not so in the case of a symposium—being an authority on some particular subject, a worker is asked if he will contribute a paper on this subject, and, though he may have nothing new to say, he hashes up some of his old published work, adds a new observation here and there, and presents his hot-house plant in order not to disappoint his friends, or, in some cases we are afraid, because he feels he must keep his name before his public and the occasion is too good an opportunity to miss.

This is not such a symposium; on the contrary with very few exceptions the papers are very live contributions to a very virile subject by men who are actively engaged in studying the blood, its functions, and its dysfunctions. Contributors include C. P. Rhoads, Russell L. Haden, C. A. Doan, E. E. Osgood, Claude Forkner, E. B. Krumbhaar, and E. Meulengracht.

Haden's study of the nature of haemolytic anaemia is particularly interesting and is very characteristic of work of this direct thinker. He starts with the red cell, its envelope, stroma, and contents, and points out that the assumption of the spherical shape allows a much bigger content for the same size of envelope, but when the contents increase beyond a certain limit the cell must burst, so that spherocytosis is a stage towards haemolysis. Comparing the functional capacity of a haemoglobin-containing disc and a sphere of equal volume, he shows that the disc with almost double the surface area for oxygen exchange is far superior.

A Call for Help

Veganin Tablets present acetyl-salicylic acid, phenacetin and codeine in synergistic combination, whereby the individual action of each constituent is greatly enhanced.

Veganin Tablets are not advertised to the public.

Supplied in tubes of 10 and 20.

A trial supply to Physicians on request.

MARTIN & HARRIS Ltd.,
Mercantile Buildings, Lall Bazar,
CALCUTTA.
Also at Bombay, Madras, Karachi
and Rangoon.

THE CALL OF PAIN

The call of pain is seldom stilled, and relief is of primary importance to the suffering patient. The paroxysmal pain of dysmenorrhoea, the persistent and intense throbbing of migraine, the shooting pains of neuralgia, the pain in affections of the bones and joints, the pain resulting from accidents — all these, and many other conditions, yield with impressive readiness to the sedative and analgesic efficacy of Veganin. With Veganin there is no systemic disturbance, no habituation. It may therefore be safely entrusted to the patient as a dependable means of relieving and preventing pain.

VEGANIN TABLETS

Prepared by WILLIAM R. WARNER & CO. LTD., LONDON, ENGLAND.

getting less than 1 per cent: this is not always the case, but old traditions die hard.

We will repeat—this is an invaluable book for the student and practitioner, as well as for the trained anaesthetist.

HANDBOOK OF ANÆSTHETICS (FORMERLY ROSS AND FAIRLIE).—Revised by R. J. Minnitt, M.D. (L'pool), D.A. (R.C.P. & S., Eng.). Fifth Edition. 1940. E. and S. Livingstone, Edinburgh. Pp. xlv plus 364. Illustrated. Price, 12s. 6d. Postage, 7d.

THIS might have been described as a handbook of inhalation anaesthetics, for more than three-quarters of the book is devoted to this subject, except that the last two chapters, on local and spinal anaesthesia by Dr. W. Quarry Wood, justify the more comprehensive title.

It is not a new book, but after total revision by a new author it almost emerges as one. The style of the writer and the treatment of the subject is concise to the extent of being terse and is not a really pleasant book to read, but it delivers the goods.

The first sixty pages are on general matters, the theory and physiology of anaesthesia, shock and anaesthesia, asphyxia, etc. Then the author gets down to work with the preparation of the patient, basal narcosis, and the various anaesthetics in common and less common (cyclopropane and vinyl ether) use. There is a chapter on oxygen, helium and CO₂ administration; this is a little disappointing for whilst there are details of the manufacture of oxygen—very interesting but with little practical bearing on the subject of the book—there are no details regarding administration, beyond a description of the apparatuses in general use, and the short paragraph on helium leaves the reviewer exactly where he was as regards his knowledge of the use of this gas, which he would have thought was almost at zero.

However, it is a practical little handbook which will be of great value to the student of anaesthetics.

DISEASES OF THE NERVOUS SYSTEM: DESCRIBED FOR PRACTITIONERS AND STUDENTS.—By F. M. R. Walshe, O.B.E., M.D., D.Sc., F.R.C.P. 1940. E. and S. Livingstone, Edinburgh. Pp. xlii plus 288. Illustrated. Price, 12s. 6d. Postage, 7d.

PROFESSOR WALSH is a well-known English authority on neurology. All students of medicine are familiar with his name for his contributions in the two popular textbooks—Price and Conybeare. His free Wednesday lecture-demonstrations at the Queen Square are always crowded with post-graduates; the reviewer had lately the fortune of being one of the crowd.

Books on diseases of the nervous system are many, but most writings are complicated with redundant terms and methods of investigations that are best interpreted by the specialist. General students and practitioners need not grapple with them all, but it is difficult for them to undertake the task of selection, of emphasis, and specially of omission. Dr. Walshe has now produced the ideal book, lucid and easy to read. Common diseases of the nervous system have been dealt with in a simple way with special reference to diagnostic methods and treatment, avoiding complexities, such as descriptions of hypothetical views, synonymous signs and syndromes, ventriculograms, electro-encephalograms, etc.

The book is planned in two sections; the first part deals with the principles of neurological diagnosis with summary descriptions of the characteristic symptom-complexes of diseases of the nervous system. In the second are given the accounts of the common diseases, the details depending on the relative importance of each in practice. Certain subjects, *viz.*, Argyll Robertson pupil, muscular atrophies, etc., have been discussed very clearly. All the latest therapeutic measures have been mentioned and the author has given cautionary comments in appropriate places, *e.g.*, 'Recently the claim has been made that the administration of vitamin E (tocopherol acetate) in doses of 3 mgm. thrice daily rapidly checks the progress of motor neuron disease.... So far, this claim has not been confirmed

and should be accepted with the very greatest reserve. . . . Massage is no more than a placebo, while to stimulate the weakening and wasting muscles by electrical currents is obviously to whip a tired horse.'

This is a really good book and fulfils the needs of general practitioners and students.

R. C.

THE COMPLEAT PEDIATRICIAN: PRACTICAL, DIAGNOSTIC, THERAPEUTIC AND PREVENTIVE PEDIATRICS.—By Wilbert C. Davison, M.A., D.Sc., M.D. Third Edition. 1940. Duke University Press, Durham, N.C. Pp. vi plus 256. Price, \$3.75 by cheque with order, or for \$4.00 on credit

WHAT French's 'Index of Differential Diagnosis' and Robert Hutchison's 'Index of Treatment' are to general medicine this book is to pediatrics. It brings all the good features of the above books into one volume, and adds many original features of its own. It is absolutely up to date, even containing references to sulphathiazole, a drug which has only arrived in India in commercial quantities within the past few weeks.

The reviewer happens to possess a copy of the first edition of this book published in 1926, then called 'Pediatric Notes'. The amount of knowledge contained in the two books may be aptly compared with that contained in an infant's brain and that in a full-grown adult's. The book has grown out of all recognition and its usefulness has increased a thousandfold.

It contains up-to-date details of laboratory tests, including those used for tropical diseases, bacteriological procedures, and culture media in common use. Diet tables and recipes for preparing foods, diabetic diets, chemical analysis of prepared foods and elimination diets for use in allergic conditions are all included. In fact, it is difficult to find any fact that one is likely to need that is not included in this amazing book.

When using the index, the American spelling is sometimes a little delaying to one accustomed to English spelling. To quote one example, one looked for 'amebic dysentery' and found it spelt 'amebic'. Another point where American practice deviates from the British is in their weights and measures, and a warning is necessary to those using the tables of equivalents in chapter XIII. In these tables, the author uses the abbreviation 'oz.' for the apothecaries ounce of 480 grains, whereas in British terminology the symbol ʒ is used, the abbreviation 'oz.' being restricted to the avoirdupois ounce of 437.5 grains. How one wishes the metric system was universally adopted to avoid all possibility of confusion and error! The metric system is used as standard in this book and the above applies only to the tables mentioned.

This review can give only a minute idea of the vast store of knowledge gathered together in this book. The best recommendation that the reviewer can give is to say that this book has found a permanent place on his desk for reference purposes.

J. F. C.

THE NEWER NUTRITION IN PEDIATRIC PRACTICE.—By I. Newton Kugelmass, B.S., M.A., M.D., Ph.D., Sc.D. 1940. J. B. Lippincott Company, Philadelphia and London. Pp. xi plus 1155, with 183 illustrations. Price, 55s.

DIET is of greatest importance in relation to the growth of a child. The biochemists have now provided us with vitamins from A to T and with knowledge of various forms of metabolism, and have demonstrated the important part they play in various diseases. Unfortunately, there is scarcity of books that correlate all the recent facts from the biochemical laboratory with clinical medicine and applied therapeutics. Consequently this newer form of medical investigation and management is apt to be neglected.

Dr. Kugelmass has brought out this book to apply the newer knowledge of nutrition derived from modern experimental science to everyday practice of pediatrics. It is divided into three main sections: the first part, devoted to nutritional physiology, deals with various

FEB., 1941]

REVIEWS

subjects such as basis of growth, food energy, calorie requirement, vitamins, digestion, absorption, metabolic processes, etc. The second section deals with nutrition in health, and presents established principles and procedures for the advancement of health and the prevention of disease. Infant feeding, infant formulas and child nutrition have been thoroughly discussed in this connection. The last section deals with most of the disorders of infancy and childhood in terms of nutrient causation. Systemic disturbances primarily affected by nutritional factors and regional diseases secondarily related to diet have also been dealt with in this section.

There are numerous tables, charts and illustrations. The dietary management of disease has been exemplified by calculated English diets for different age groups. Selected references have been given at the end of each chapter.

The book provides a mine of information and no pediatrician can afford to be without it.

R. C.

SURGERY OF THE HAND.—By R. M. Handfield-Jones, M.C., M.S., F.R.C.S. 1940. E. and S. Livingstone, Edinburgh. Pp. viii plus 140, with 95 illustrations including several in colour. Price, 15s. Postage, 6d.

WITH the increasing participation of this country in the war and the expansion of industry, surgical conditions of the hand are bound to become commoner. In the opening chapters of this book we read that of the injuries sustained by employees in Great Britain's heavy industries over 60 per cent are hand injuries. The author quotes some impressive figures to show how both worker and industry benefit from proper medical control. An outline is given of methods that are proving successful in Great Britain, and they are adaptable with little modification to conditions in India.

The first half of the book is taken up with the infections of the hand and the restoration of function. The modern approach to these problems is explained in a straightforward manner, and many old misconceptions and incorrect methods of treatment receive their *coup de grâce*. Movement of affected fingers from a very early stage is given as the secret of a good final result. The sling and the finger-stall are regarded as menaces, and manipulation of stiff fingers is not advised except in special circumstances.

In the second section, injuries of the hand are dealt with, beginning with fractures. In discussing the question of tendon suture, differentiation is made between the treatment of free and ensheathed tendons. Adhesions or sepsis will surely follow if suture of ensheathed tendons is not postponed until all signs of inflammation have disappeared. Primary suture of free tendons is worth attempting if the wound is clean and has received attention within eight hours.

A test for latent sepsis is given for employment before secondary suture is undertaken.

The last section describes congenital and acquired defects, and tumours of the hand.

The text, clarified by illustrations rather than by case notes and experimental work, occupies no more than 134 pages. But it has been most carefully prepared and beautifully published. It should have a wide appeal, but it is specially recommended to casualty surgeons and medical officers of industrial concerns.

W. McN. N.

ILLUSTRATIVE ELECTROCARDIOGRAPHY.—By Julius Burstein, A.B., M.D. Originally written by the Late J. H. Bainton, A.B., M.D., and J. Burststein, A.B., M.D. Second Edition. 1940. D. Appleton-Century Company, Incorporated, New York, and London. Pp. xviii plus 292, with 106 plates. Price, 25s.

THE first edition of this well-known book on electrocardiography was reviewed in this journal in the July issue in 1935. In this, the second edition, the book

has been brought up to date by the inclusion of newer developments in the subject of electrocardiography. Recent developments in electrocardiographic diagnosis of coronary occlusion and myocardial disease, and an exhaustive description of the subject of precordial leads are the chief additions. Inclusion of the electrocardiographic changes in acute cor pulmonale, in chronic right ventricular strain, P-wave change in left auricular stress, and a more detailed description of chronic left ventricular strain, would have further enhanced the value of this book.

The reviewer feels that this edition will maintain the popularity that it gained by its simple descriptive style and the excellence of its illustrations.

P. C. S. G.

ESSAYS ON CARDIOLOGY.—By Dr. Jal Gopal. Published by the 'Indian Medical Journal', 131, Coral Merchant Street, Madras. Pp. 192. Illustrated. Price, Re. 1

THIS volume presents seventeen essays on some of the more important aspects of cardiology, and although the author makes no claim for erudition or completeness, yet they are so presented as would evoke the interest of the general practitioner in the subject. The essays were published in the columns of the *Indian Medical Journal*, the journal of All-India Licentiates' Association and the book is the compilation of these essays in a single volume.

The publishers cannot be congratulated on the get-up of this book. With slightly increased cost, they might have prevented this book from being a number of reprints stitched together and indifferently bound.

L. G. G.

PATHOLOGICAL HISTOLOGY.—By Robertson F. Ogilvie, M.D., F.R.C.P. (Edin.). E. and S. Livingstone, Edinburgh. Pp. x plus 332, with 220 photomicrographs in colour. Price, 27s. 6d. Obtainable from Messrs. Butterworth and Company (India), Limited, Bombay and Calcutta. Price, Rs. 18-8-0

WHEN one says that the outstanding feature is the illustrations, it is not a criticism of the part the author has played in the production of this excellent book; in fact we believe that he would be the first to agree that Mr. P. C. Dodds' photomicrographs and their reproduction by Graphic Art Limited of London have made his book.

There are over two hundred really remarkable reproductions of coloured photographs of pathological sections, with concise but adequate descriptions below them, which really do show what they are meant to show, and simplify the interpretation of the sections issued to students in such a way as to make the reviewer almost wish that he had been born thirty years later.

The arrangement of the book is orthodox, and very satisfactory; the first chapters are on disturbances of nutrition, disturbances of circulation, inflammation and repair, septic inflammations, and tumours. Then the special systems are dealt with, each in a separate chapter.

The reviewer obtained some satisfaction from the fact that in a book with such a high standard of illustration the reproductions of the photographs of individual blood cells were not any clearer than those illustrating his own paper that appeared in this journal last month, and about which he was very disappointed at the time.

The chapter on the haemopoietic system is a very good one and the origin of the various cell types seen in the peripheral blood in health and disease is clearly described. The author follows the usual British system in making the megaloblast only an embryonic and pathological cell; he describes the primary erythroblast as arising directly from the common stem cell, the haemocytoblast from which myeloblasts, monoblasts and lymphoblasts also arise. Whilst acknowledging that this is the usual teaching in Great Britain, we believe that there is a non-haemoglobinized cell more primitive

than the author's primary erythroblast (whose nucleus according to his description has no nucleoli), but which is nevertheless a differentiated cell of the red-cell series; this cell is the 'megaloblast' of the Sabin school.

It is a book that no teacher of pathological histology should be without and to the student who can afford to buy a copy we strongly recommend it as very good value indeed for the money.

ELEMENTARY ATLAS OF HISTOLOGY.—By Burton Bradley, M.B., Ch.M. (Syd.), M.R.C.S. (Eng.), L.R.C.P., D.P.H. 1940. Angus and Robertson Limited, Sydney. Pp. x plus 122. Price, 15s.

THE author is an experienced teacher of long standing and naturally he has studied the difficulties of the students. He has very correctly pointed out that the students in their practical class work have got to take a 'great deal as granted because their specimens in the class are not always fully representative ones. So it is good for them to get some typical pictures which can be readily consulted on the working bench. For those who have just started to visualize the complications of the animal structures, it is necessary that they must have a picture in front of them to let them understand what they are expected to see under the microscope. Bigger volumes are often discouraging to the students because of their size and are often apt to be left at home. The present atlas is very handy and contains most of the pictures required by a medical student. From the above points of view this small atlas of histology will be of help to the students.

B. P. T.

ELEMENTARY PATHOLOGICAL HISTOLOGY.—By W. G. Barnard, F.R.C.P. Second Edition. 1940. H. K. Lewis and Company, Limited, London. Pp. x plus 75, with 181 illustrations (including 8 in colour) on 54 plates. Price, 10s.

FROM the students' point of view, very few branches of medical science require the help of photographs, diagrams, illustrations, etc., as much as the subject of morbid histology. Hence I welcome the second edition

of Barnard's small handbook on pathological histology. It will help immensely the students on the working bench and reading table as a ready reference. Of course, the students should be warned that this small volume cannot in any way be allowed to replace a textbook on the subject and it must not be forgotten, as rightly pointed out by the author, that it is an elementary one. The chosen size of the pictures is very happy because they enable the students to visualize the changes that have occurred in a wider area. Inclusion of more high-power pictures would have been very helpful. Some of the lower-power pictures, as for instance the figures 36, 37 and 49, do not convey much idea to the students for want of detail. Combination of low-power and high-power pictures, as adopted in figures 23 and 24, should have been more followed. It is doubtful whether inclusion of a few sporadic atypical pictures, such as atypical squamous cells carcinoma (figures 130 and 131) and the Wilms tumour (figure 145), is necessary in a handbook which is very elementary in nature. In the tumour section the nerve tissue tumours and group of teratomatous tumours are missed.

However, considering the vastness of the subject, a book of this size which is nevertheless comprehensive will be much appreciated. The author should be congratulated, especially for his preface to the first edition which is true in every way.

B. P. T.

NEUROSYPHILIS (SYPHILIS OF THE NERVOUS SYSTEM).—By C. Worster-Drought, M.A., M.D. (Cantab.), F.R.C.P. (Lond.). 1940. John Bale, Sons and Staples, Limited, London. Pp. xlv plus 241. Illustrated. Price, 10s. 6d.

THIS monograph is a valuable addition to syphilology. References are plentiful and so are the author's personal observations. Lucid accounts have been given of Spatz's test, fixed pupil, myotonic pupil with areflexia, and the significance of Wassermann's and Lange's reactions. Illustrations are excellent. Skigrams showing tabetic arthropathies compatible with a patient's usual life are specially informative.

The format is good and price reasonable.

Correspondence

A CASE OF YAWS

SIR.—I enclose herewith four photographs of a case of yaws from the Kamrup district of Assam where this disease is endemic.

The photographs are so exceptionally clear, and the eruption so unusually developed that I thought you might wish to reproduce them in the *Indian Medical Gazette*.

No. 1 photograph shows the distribution of the eruption on the anterior surface of the body.

No. 2 shows the distribution on the posterior surface.

No. 3 shows a detailed view of the eruption on the head and shoulders.

No. 4 shows the same patient after treatment with a course of N.A.B. totalling 4.95 grams. Apart from the complete disappearance of the eruption, the improvement in the general condition of the patient is very noticeable.

The photographs were taken for me by the Sen Studios, Gauhati, Assam.

E. S. PHIPSON, C.I.E., D.S.O., M.D., F.R.C.P., COLONEL, I.M.S.

A CHEAP FLUSH-OUT LATRINE

SIR.—May I trespass on your space in one matter? On page 677 of your November issue, you have a short article on a flush-out type of latrine. My experience here with septic tanks and bore-holes is that the

type Dr. Rangaswami has described is by far the best. So much so, that we have had a number in use here now for close on six years with absolutely no trouble of any sort during that period. The septic tank type we have again and again had trouble over. Also the open type bore-hole which in some cases has caved in during the rainy season and has often attracted flies, mosquitoes, etc. With the covered large bore-hole type outside, connected to a flush closet inside there is simply nothing to go wrong.

A 14-inch bore-hole auger, bought in Calcutta for Rs. 82, had its cutting edge worn off in our hard soil making three holes. A hole 7 feet by 20 feet can be dug by four men at a cost of Rs. 5, bricked by 10-inch bricks, covered, and connected to an inside squatting pan, with a small, 5-inch or 3-inch brick reservoir for water at its side; it will require no attention for years.

Service Notes

APPOINTMENTS AND TRANSFERS

THE VICEROY AND GOVERNOR-GENERAL has been pleased to make the following appointment on His Excellency's personal staff:—

To be Honorary Surgeon

Colonel H. J. M. Cursetjee, D.S.O., vice Colonel D. F. Murphy, M.C., vacated 8th November, 1940.

On return from leave Lieutenant-Colonel H. M. Salamatullah is reverted to military service.

Lieutenant-Colonel W. Aitchison, Civil Surgeon, on return from leave is posted as Civil Surgeon, Allahabad.

Lieutenant-Colonel A. H. Shaikh, Superintendent, Central Prisons, Bareilly, is appointed as Inspector-General of Prisons, United Provinces, with effect from the 1st October, 1940.

Lieutenant-Colonel J. P. Huban, O.B.E., Administrative Medical Officer in Rajputana, is appointed to officiate as Additional Deputy Director-General, Indian Medical Service, with effect from the 4th December, 1940, vice Lieutenant-Colonel R. F. D. MacGregor, C.I.E., M.C., granted leave.

Major E. S. S. Lueas, Civil Surgeon, is transferred from Allahabad to Dehra Dun.

The services of Major W. J. Moody, an Agency Surgeon, are temporarily placed at the disposal of His Excellency the Commander-in-Chief, with effect from the 4th December, 1940.

Major S. C. H. Worsdene, Civil Surgeon, Dehra Dun, reverted to military service, with effect from the 9th December, 1940.

On return from leave Major G. F. Taylor resumed charge of the office of Professor of Clinical Medicine, K. E. Medical College, Lahore, on the forenoon of the 16th December, 1940.

On recall to military duty Major P. C. Dutta, Civil Surgeon, Ferozepur, made over charge of his civil medical duties, on the forenoon of the 16th December, 1940.

Major G. B. W. Fisher, Resident Medical Officer, Eden Hospital, Calcutta, is appointed to be 1st Resident Medical Officer, Presidency General Hospital, Calcutta, vice Captain W. M. Niblock.

Major W. McAdam, Civil Surgeon, Taunggyi, on transfer, made over and Major A. E. Kingston received charge of the duties of Civil Surgeon, Taunggyi, Southern Shan States, on the afternoon of the 27th December, 1940.

The services of Captain J. W. D. Goodall, 2nd Resident Medical Officer, Presidency General Hospital, Calcutta, are placed at the disposal of the Government of India in the Defence Department.

Captain W. M. Niblock, 1st Resident Medical Officer, Presidency General Hospital, Calcutta, is appointed to be 2nd Resident Medical Officer of the same institution, vice Captain J. W. D. Goodall reverted to military duty.

PROMOTIONS

Lieutenant-Colonel to be Colonel

C. H. N. Baker, M.C. Dated 8th November, 1940,
 with seniority 31st July, 1936.

Major to be Lieutenant-Colonel

W. Aitchison, M.C. Dated 20th December, 1940.

The seniority of the undermentioned Majors in their present rank is antedated to the dates stated below:—

L. G. Backhurst. Dated 10th May, 1937.
 D. C. Chopra. Dated 19th May, 1937.
 J. Singh. Dated 19th May, 1937.
 E. A. R. Ardesir. Dated 16th June, 1937.
 H. S. Waters. Dated 4th August, 1937.
 J. H. Boulbee. Dated 29th October, 1937.
 J. P. J. Little. Dated 30th October, 1937.
 E. A. O'Connor. Dated 30th October, 1937.
 P. L. O'Neill. Dated 30th October, 1937.
 G. R. M. Apsey. Dated 22nd November, 1937.
 B. Temple-Raston. Dated 22nd December, 1937.
 V. E. M. Lee. Dated 1st February, 1938.
 G. B. W. Fisher. Dated 2nd February, 1938.
 E. P. N. M. Early. Dated 6th February, 1938.
 D. Tennant. Dated 1st March, 1938.
 D. P. Mitra. Dated 1st March, 1938.
 T. D. Ahmad. Dated 6th April, 1938.
 M. Jafar. Dated 9th April, 1938.
 B. N. Khan. Dated 2nd May, 1938.
 A. M. Chaudhuri. Dated 6th May, 1938.
 W. Happen. Dated 2nd August, 1938.
 H. J. Curran. Dated 4th August, 1938.
 W. P. Lappin. Dated 4th August, 1938.
 B. J. Griffiths. Dated 4th August, 1938.
 J. H. Gorman. Dated 4th August, 1938.
 M. H. Shah. Dated 10th August, 1938.
 R. T. Hicks. Dated 22nd October, 1938.
 A. M. Sheridan. Dated 29th October, 1938.
 P. V. Bamford (since deceased). Dated 15th January, 1939.
 K. Jilani. Dated 26th January, 1939.
 D. H. Waldron. Dated 6th February, 1939.
 C. H. Dhala. Dated 8th February, 1939.
 S. Narain. Dated 25th February, 1939.
 D. Datt. Dated 10th April, 1939.
 B. L. Taneja. Dated 19th May, 1939.
 W. J. Moody. Dated 6th June, 1939.
 S. W. H. Askari. Dated 3rd July, 1939.
 A. B. Guild. Dated 4th August, 1939.

Captain Fateh Mohammad Khan, Health Officer, Simla, has been promoted to the rank of Major, with effect from the 3rd April, 1940.

RETIREMENT

Lieutenant-Colonel N. C. Kapur. Dated 21st October, 1940.

Notes

DAGENAN—M. & B. 693

REDUCTION IN PRICE

We are informed by the makers of DAGENAN—M. & B. 693, Pharmaceutical Specialities (May and Baker), Limited, Dagenham, that a reduction in the price of this drug has now become effective. The new prices, which are subject to the usual medical discount, are as follows:—

Rs.
<i>Dagenan—M. & B. 693</i>
Containers of 25 X 0.50 gm. tablets .. 4-12
" 100 X 0.50 " .. 18-7
" 25 X 0.125 " .. 2-11
Boxes of 6 X 2.50 c.c.m. ampoules 20 per cent oily suspension .. 4-4
<i>Dagenan sodium—M. & B. 693 soluble</i>
Boxes of 6 X 3 c.c.m. ampoules 33½ per cent solution .. 7-5
Boxes of 25 X 3 c.c.m. ampoules 33½ per cent solution .. 28-0

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints gratis; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

The preparation of reprints entails rearranging the type, so that there is often a delay of a month or more, after the publication of the *Gazette*, before the reprints are ready. If reprints are not received within two months of publication of the *Gazette*, contributors should write to the Publishers.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

PNEUMOCOCCAL PERITONITIS : WITH REPORT OF A RECOVERY WITH M. & B. 693

By W. B. ROANTREE, M.A., M.D. (Dub.), F.R.C.S. (Ed.)
Chief Medical Officer, Kolar Gold Fields Hospital
and

A. CAPLAN, M.D. (Lond.), M.R.C.P. (Lond.)
Senior Medical Officer at the Hospital

THE comparative rarity of pneumococcal peritonitis, its high mortality, its peculiar problems of diagnosis, and differences of opinion as to the place of surgery in its treatment, combine to make it a disease of unusual interest. In this article an abstract of the literature of pneumococcal peritonitis is given and a report is included of an early case which was treated with remarkable success by M. & B. 693 after operation. The rapidity with which symptoms disappeared with this treatment is considered to justify the publication of a single case of an uncommon disease which in the past has been very fatal.

Incidence.—The rarity of pneumococcal peritonitis is illustrated by the relatively few cases seen by individual surgeons. Barrington-Ward (1932) has personally observed 20 cases over a period of 15 years. Newell (1939) records 36 cases admitted to the Harriet Lane Home for children in 25 years.

Sex incidence.—The great preponderance of the female sex in cases of primary pneumococcal peritonitis is well known. McCartney and Fraser (1922) record 56 cases all of which were females. Newell (*loc. cit.*) however states that there is no significant difference in incidence between the sexes, and in his series of 12 cases of this form of the disease 7 were females and 5 were males; but this experience is counter to that of most writers, who attach diagnostic importance to the sex. In the secondary form either sex may be affected.

Age incidence.—The limits commonly recognized are between 1 and 10 years with a maximum incidence of 3 to 7 years; very occasionally adults are affected.

Mortality.—The high mortality of pneumococcal peritonitis is a constant characteristic of acute cases described in the literature; the figures become considerably lower in the late stages of the disease when their interpretation is obscured by the question of survival ratio. As an illustration of the mortality of the diffuse form of pneumococcal peritonitis, Carson (1924) quotes one series of 46 cases with 86 per cent mortality, and another of 45 cases with 100 per cent mortality. Loutsch and Mérigot (1934) describe 10 cases with a mortality of 40 per cent.

Lipshutz and Lowenburg (1926) report 23 cases of pneumococcal peritonitis and streptococcal peritonitis in children under 6 years of age, each with a mortality of 100 per cent. Newell (*loc. cit.*) states that in the literature the mortality of pneumococcal peritonitis averages from 40 per cent to 65 per cent and the 36 cases of pneumococcal peritonitis which he reports had a mortality of 61.1 per cent.

Pathogenesis.—The usual classification of the disease is into primary, or idiopathic, and secondary. In the secondary form the focus of origin is known, whereas in the primary the evidence on this point is conflicting.

The portals of infection may be :—

- (i) the female genital tract,
- (ii) upper and lower respiratory tracts, including the middle ear,
- (iii) the intestinal tract.

The pneumococci reach the peritoneal cavity either by local spread, e.g., from the female genitalia (as in the case described in this paper) or the bowel, or by the blood-stream as part of a septicæmia, the peritonitis in the latter event being a local manifestation of a general disease. Newell (*loc. cit.*) and Lazarus (1932) draw attention to a group in which nephrosis is the predisposing cause.

Pathological appearances.—The pathological picture varies with the stage of the disease. The earliest appearances in cases of primary pneumococcal peritonitis are those of pelvic peritonitis with salpingitis; the visceral and parietal peritoneum of the pelvis and lower ileum are intensely congested and a small amount of free fluid may be found. The fallopian tubes are acutely inflamed and oedematous, patches of purulent exudate adhere to them, and pus may be expressed from the fimbriæ. The pneumococcus in pure culture can be obtained from both exudate and tubes. It is noteworthy that type I pneumococcus has been recovered in the vast majority of cases of primary pneumococcal peritonitis. After 24 hours the peritonitis tends to spread and the exudate becomes purulent after the fourth day. In the secondary form of the disease the peritonitis is generalized from the outset. From about the fourth to the twelfth day the general peritoneal exudate is purulent, greenish in colour, and contains flakes of fibrin. If this stage is survived localization usually follows and the late stage of encysted-abscess supervenes. Such abscesses are commonly situated in the pelvis and may be loculated; if untreated they tend to discharge spontaneously through the umbilicus.

Clinical manifestations.—Clinical manifestations will depend upon the virulence of the infection. In the acute and commoner form of pneumococcal peritonitis the disease may progress to a rapidly fatal issue, whereas in the subacute form the onset may be insidious and localization of the peritonitis with abscess

formation is more likely to occur. The characteristic symptoms are : acute abdominal pain, vomiting, diarrhoea, pyrexia, and occasionally dysuria and tenesmus; the onset may be succeeded by a temporary improvement. Abdominal pain is a prominent complaint and may be peri-umbilical, sub-umbilical, or referred to either iliac fossa; the pain may be intermittent, especially in subacute cases. The frequency of diarrhoea is emphasized by many authors.

On examination the patient is found to be acutely ill, drowsy or perhaps even delirious, with an anxious facies and a tinge of cyanosis. Pyrexia is usually well marked, temperature 102°F. to 104°F., but it is important to note that sometimes it may be mild or even absent. Respiration and pulse rates are rapid. The abdomen which may be distended is found to exhibit limitation of movement on respiration. Tenderness and rigidity may both be present in the lower abdomen including the iliac fossæ, and will be noticeably indefinite. The contrast between the somewhat indefinite local abdominal findings and the severe general toxæmia is a feature of the condition. Leucocytosis is high, 20,000 to 40,000 cells per c.mm., with a high proportion of polymorphonuclear cells. Late stages of the disease are characterized by remittent pyrexia, wasting, abdominal distension, perhaps with local collections of pus in the lower abdomen, and marked absence of abdominal rigidity; an abscess may be pointing at the umbilicus.

Differential diagnosis.—The difficulties of diagnosis are so great that in the majority of cases a pre-operative diagnosis has not been made. Signs suggestive of peritonitis in a young female child, especially if accompanied by marked pyrexia, diarrhoea and a high polymorphonuclear leucocytosis, should always raise the suspicion of pneumococcal peritonitis in the examiner's mind and this may lead to confirmation of the diagnosis by peritoneal puncture, thus obviating the unnecessary hazard of a major operation. Positive findings provided by peritoneal puncture are the only certain means of making the diagnosis without operation. In this procedure a spinal needle is introduced into the peritoneal cavity with the object of obtaining at least a few drops of fluid for examination. The puncture may be made internal to the left anterior superior iliac spine with the child on its back, or as suggested by Duncan (1931) in the mid-line midway between the umbilicus and symphysis pubis with the child in the prone position. An alternative point of entry recommended by Loewe (1932) is through the posterior vaginal fornix. Bacteriological examination of the vagina is recommended by Kirchhoff (1930), and if this is positive for pneumococci it may be of assistance in the diagnosis.

In approaching the problem of diagnosis it must first be decided whether the patient is

suffering from peritonitis or not. Lobar pneumonia with peritonism may simulate peritonitis very closely; physical signs in the chest may be absent or misleading; rapid respiration, cyanosis, high pyrexia and leucocytosis may be present in both conditions. The indefinite rigidity in primary pneumococcal peritonitis may further confuse the diagnosis. It has also to be borne in mind that secondary pneumococcal peritonitis may arise as a complication of lobar pneumonia. Therapeutically the immediate differentiation is unimportant, M. & B. 693 being indicated in both conditions.

In this country abdominal pain and diarrhoea with moderate or high pyrexia are frequent symptoms of dysentery, and may be suggestive of enteric, both relatively very common diseases. Dysentery can readily be excluded by examination of the abdomen and faeces, and pneumococcal peritonitis can immediately be distinguished from enteric by the leucocyte count. Confirmatory evidence of enteric will be furnished by blood-culture, agglutination tests, etc. In cases with an enteric perforation the clinical picture is dominated by collapse. In severe cases of pneumococcal peritonitis in which drowsiness is a prominent sign meningitis may have to be excluded by lumbar puncture.

When a diagnosis of peritonitis has been made it is necessary to determine its aetiology owing to the urgent necessity for surgical treatment in cases in which it is secondary to appendicitis. When local abdominal signs are inconclusive, the following points may be helpful in establishing the diagnosis. Appendicitis is the commonest cause of peritonitis in children and the sexes are affected equally. High pyrexia and leucocytosis are more usual in pneumococcal peritonitis than in appendicular peritonitis, and whilst diarrhoea may occur in pelvic peritonitis secondary to appendicitis, it is more characteristically a symptom of pneumococcal peritonitis. In cases of doubt peritoneal puncture should be performed, and unless positive findings are obtained exploratory laparotomy is indicated.

In primary streptococcal peritonitis symptoms and signs may be indistinguishable from pneumococcal peritonitis. The condition is very uncommon, occurs mainly in the first year of life, attacks both sexes equally, and a positive diagnosis can be made by peritoneal puncture. The differentiation is to some extent academic, for both conditions may be successfully treated in the early stages by M. & B. 693.

The later stages of pneumococcal peritonitis may be difficult to distinguish clinically from the more acute forms of tuberculous peritonitis.

Treatment.—Prior to the introduction of M. & B. 693 in the treatment of pneumococcal peritonitis, controversy centred on the advisability or otherwise of immediate operation in early cases. Fraser was the chief supporter of conservative treatment provided that the diagnosis was certain. All authorities were agreed on the value of specific serum therapy at this

stage, and on the need for surgical treatment when localization of the infective process had occurred.

Chemotherapy.—Many reports have already appeared in the literature on the value of M. & B. 693 in the treatment of pneumococcal peritonitis (Gaisford, 1940; Maughan, 1940; Banks and Joseph, 1940) and evidence is accumulating that the place of M. & B. 693 in the treatment of this condition is clearly established. In the earliest stages when the infection is localized to the pelvis or before the general peritoneal exudate has become frankly purulent, surgery is contraindicated and the exhibition of M. & B. 693 in sufficient dosage should lead to complete resolution. Even when diffuse peritonitis with suppuration is present surgery should be withheld—provided the diagnosis is certain—and M. & B. 693 will be of value in combating the coincident septicaemia and assisting in the localization of the disease. Clinical experience in the treatment of severe pneumococcal diseases, especially those associated with a high mortality rate, such as meningitis and peritonitis, has shown that massive initial dosage is essential. The exact dose to be administered and the route and spacing of doses will depend almost entirely on the severity of the disease and the degree of toxæmia. Due regard must be given to the age of the patient, although it is a notorious fact that the relative dose for a child is weight for weight proportionately greater than for an adult. The degree to which children may tolerate massive doses of M. & B. 693 is well illustrated in a case described by Falla (1940) of pneumococcal meningitis in a child of seven successfully treated with this drug. Intramuscular M. & B. 693 soluble was given in doses of 1 gramme hourly during the first 24 hours, and repeated in this dosage during the third day of treatment, a total of 48 grammes being given in 5 days. It is generally agreed that fulminating cases of pneumococcal infections should receive the initial doses of M. & B. 693 parenterally, the intramuscular route being most convenient in a child. Banks *et al.* (1940) strongly advocate intravenous administration (3 c.cm. M. & B. 693 soluble to 9 c.cm. of saline), and emphasizes the dangers of muscle necrosis in intramuscular therapy. One of us (A. C.) has recently treated a number of cases of lobar pneumonia with repeated doses of M. & B. 693 soluble intramuscularly, and has never seen muscle necrosis nor severe pain follow. The value of parenteral administration, especially in young children, is self-evident; the possibility of defective absorption is excluded, the exact quantity of the drug absorbed is known, and therapeutic action is more rapid. Dosage may be regulated by estimating the blood concentration of M. & B. 693, about 10 mgm. per cent being desirable; although Flippin *et al.* (1939) found in pneumonia patients that the therapeutic action appeared to be as good in patients

with low concentrations as in those with high concentrations.

The following suggestions are made for the administration of M. & B. 693 in the treatment of pneumococcal peritonitis. The doses given are for children over 5 years of age; in children under 5 the doses should be halved.

Initial dosage.—One to 2 grammes at 2 to 4 hourly intervals depending on the severity of the disease. In fulminating cases the drug should be given intramuscularly or intravenously. In all cases it is desirable to give the first 2 or 3 doses during the first 24 hours parenterally until improvement in the general condition permits oral administration. ‘Loading’ the first and second doses by an additional half gramme may be found necessary in certain cases. The drug may be continued in this dosage for 24 to 72 hours depending on the response to treatment.

Maintenance dosage.—When a response is apparent the dose may be reduced to 0.25 to 0.5 gramme 4-hourly and continued for 48 hours after the patient has become afebrile, provided toxæmia is absent. Occasionally a relapse may occur after an initial response, and reversion to the initial massive doses may become necessary. The course of treatment need rarely extend beyond 6 or 7 days. The total amount given will obviously depend on the severity of the disease and the duration of treatment. The case described in this paper needed comparatively small doses over a short period, 4.75 grammes being given over a period of 72 hours. Severe cases in older children, however, may require 30 to 50 grammes during 6 or 7 days of treatment.

Serotherapy.—The value of serum therapy as an adjuvant to M. & B. 693 in the treatment of pneumococcal infections has yet to be determined. Anti-pneumococcal serum is costly, and except in gravely ill patients should rarely be necessary if adequate doses of M. & B. 693 are given. The commonest organism found in primary pneumococcal peritonitis is type I pneumococcus, and for this reason type I serum should be given until the pneumococcus isolated has been typed. Newell (*loc. cit.*) suggests that rabbit serum may be more efficacious than horse serum, basing this statement on experimental work done by Horsfall *et al.* (1937) in cases of pneumococcal empyema. These workers found that rabbit serum antibodies diffused more readily into pleural exudates than horse serum. Doses as large as 300,000 units daily have been given intravenously.

Surgical treatment.—The difficulty of making a certain diagnosis of pneumococcal peritonitis has already been alluded to, and surgical treatment in the early stages of the disease is restricted to cases in which the diagnosis remains in doubt. As yet the most important condition to be excluded by laparotomy is peritonitis arising from the appendix, a simple muscle-splitting incision in the right iliac fossa

is preferable to a paramedian incision, although in cases where the patient is not gravely ill the latter may be justified. A gridiron incision permits of appendicectomy and drainage through a counter incision in appendicular cases; and sufficient access to explore the pelvis and make a bacteriological examination with the minimum of disturbance in other cases. All are agreed on the necessity for conservative surgery in later stages of the disease, and when the pus has become localized simple drainage is required. The post-operative treatment is conducted on ordinary general surgical lines; special measures including small blood transfusion, and fluids intravenously, intramuscularly, or subcutaneously, should be given if required.

Case abstract

A. P., a female Anglo-Indian child, aged 3 years and 5 months, was admitted into the Kolar Gold Fields Hospital on 9th October, 1940, complaining of abdominal pain and vomiting.

The child's previous history was unimportant. The present illness began at 11 p.m. the night before admission with abdominal pain referred to the lower abdomen; the pain persisted for about half an hour, recurred six hours later with increased severity and continued in this form for a further nine hours after which the child was brought to hospital. Vomiting occurred twice during the day; the bowels were not moved.

On examination the child was mildly toxæmic, alert, and apprehensive of abdominal examination. The breathing was shallow and rapid; temperature 100°F., pulse 160, respiration 56. The abdomen, which was not distended, showed much restricted respiratory excursion in its lower part, and considerable generalized deep tenderness with indefinite maximal localization in the right umbilical region, and moderate lower abdominal rigidity, possibly more marked on the right than the left. Liver dullness was present. No abnormality was found in the chest; there was no otorrhœa; and the tympanic membranes were normal on both sides.

An enema produced a satisfactory result without alleviation of symptoms. The patient was put in Fowler's position and kept under observation. On the following morning toxæmia had increased; the temperature had risen to 101.5°F., the pulse being 148. The alæ nasi were in full use. On examination the abdomen moved less freely on respiration than on the previous day, tenderness had increased noticeably and was doubtfully maximal in the right iliac fossa. Rigidity had also increased especially in the lower abdomen and was most evident on the right side. Liver dullness appeared to have diminished. A catheter specimen of urine showed no abnormal constituents. Total leucocytes 34,000 per c.mm. Differential—polymorphonuclears 97 per cent; lymphocytes 3 per cent; large mononuclears 0 per cent; eosinophils 0 per cent. Peritonitis was diagnosed, and this was considered to be most probably of appendicular origin. Atropine gr. 1/150 was given and exploration under ether anaesthesia performed.

Operation.—Small low right paramedian incision; rectus drawn aside; no free peritoneal fluid found. The appendix was normal, and the lower ileal mesenteric glands were soft, enlarged and slightly congested. On examining the pelvis a very acute bilateral salpingitis was discovered; the tubes were much engorged and fibrinous plaques of pus were adherent to tubes and ovaries on both sides. A swab for bacteriological examination was taken from one of the purulent patches, and from this type I pneumococcus was subsequently recovered in pure culture. Appendicectomy was performed and the abdomen was closed with a small drain down to the pelvis. At the end of a brief

operation the patient appeared to have a high temperature, and some generalized twitchings suggestive of ether convulsions occurred in the face and limbs. The patient was sponged and the twitchings ceased. A vaginal smear was taken whilst the patient was still anaesthetized, and from this staphylococcus albus—probably a contaminant—was recovered. It is regrettable that a blood culture was not taken at the same time.

In addition to general measures, treatment with M. & B. 693 was started immediately. M. & B. 693 soluble 1.5 c.c.m. (0.5 grammes) was given intramuscularly before the patient left the theatre, and this was repeated in four hours' time. M. & B. 693 one tablet (0.5 grammes) was given by mouth after a further period of four hours, and thereafter one-half tablet repeated four-hourly until the drug was stopped 72 hours after operation, the total dose administered then being 3 c.c.m. (1 grammes) of M. & B. 693 soluble intramuscularly, and 7½ tablets (3.75 grammes) orally. A feature of the post-operative course was its smoothness and complete absence of any cause for anxiety. An improvement in the general condition was noted soon after the institution of treatment, the temperature fell permanently to normal within 6 hours and a fall in the pulse rate followed 24 hours later. A small amount of watery discharge was noted in the drainage tube when removed on the second day and no further discharge occurred; the wound healed satisfactorily with only slight superficial infection. The white blood cells repeated 3 days after the operation were 8,000 per c.mm. Polymorphonuclears 56 per cent; lymphocytes 40 per cent; large mononuclears 2 per cent; eosinophils 2 per cent.

The only post-operative complaint was transient suprapubic pain and tenderness noted on the 5th day. The patient was discharged 15 days after the operation in good health and free from symptoms. One month later she was seen in the out-patient department and was found to be in excellent health.

Summary and conclusions

Pneumococcal peritonitis has been discussed in its aetiological, pathological and clinical aspects. Particular attention has been paid to the difficulties of diagnosis, and clinical manifestations and treatment have been considered in some detail.

An early case of primary pneumococcal peritonitis in a female child has been described in which certain clinical features were atypical, namely, absence of high pyrexia and diarrhoea. The earliest stages of pneumococcal peritonitis were demonstrated at laparotomy, and type I pneumococcus in pure culture was isolated from the tubal exudate suggesting that the portal of entry of the pneumococcus was the genital tract. It is interesting to note that type I pneumococcus appears to be the causal organism in most cases of primary pneumococcal peritonitis. Treatment with M. & B. 693 was remarkably successful, the temperature falling to 98.4°F. within six hours of the beginning of treatment and at no subsequent period was this reading exceeded. The disappearance of toxæmia and the rapidity of resolution were correspondingly gratifying. The immediate improvement in the condition of the patient was in sharp contrast to the protracted and frequently unfavourable course of pneumococcal peritonitis recorded in the past.

One of the greatest problems in pneumococcal peritonitis is the difficulty of making a certain pre-operative diagnosis, and it seems likely that

in the future, as in the past, the correct diagnosis will be made at operation in many cases. The possibility of pneumococcal peritonitis should arise in an examiner's mind when he is confronted with a case—especially if it is a young female child—showing a combination of abdominal pain and tenderness with indefinite rigidity, toxæmia, high temperature, diarrhoea, and high polymorphonuclear leucocytosis. The suspicion of a pneumococcal peritonitis should lead to peritoneal puncture, and if the diagnosis remains in doubt after this procedure, exploratory laparotomy through a small right muscle-splitting incision is indicated.

The literature on the treatment of pneumococcal infection with M. & B. 693 contains ample evidence of the brilliancy of the results obtained by the use of this drug. The rarity of pneumococcal peritonitis, however, has resulted in comparatively few cases of this disease treated with M. & B. 693 being reported up to the present time. Such cases as have been described are very encouraging and the assumption is justified that M. & B. 693 is bound to lower the mortality—perhaps dramatically—of this hitherto very fatal disease. It seems likely that in early cases of pneumococcal peritonitis timely and adequate administration of M. & B. 693 will lead to complete resolution and in later cases will permit the natural defences of the body to localize the disease. Attention has been drawn in this paper to the value of M. & B. 693 soluble during the initial stages of treatment.

At the early stages surgery is contraindicated, but in late cases with local collections of pus, surgical drainage is a necessity, and it is unlikely that M. & B. 693 will have any effect on such cases unless septicaemia is present.

The authors are well aware of the fallacy of basing conclusion on a single case, but the example described in this article is not an isolated report, and is presented as a link in a growing chain of evidence of the value of M. & B. 693 in the treatment of pneumococcal peritonitis.

PNEUMOCOCCAL PERITONITIS

By M. N. DE, M.B. (Cal.), M.R.C.P. (Lond.)
Professor of Medicine, Medical College, Calcutta
and

MD. IBRAHIM, M.B., B.M.S.
Senior House Physician, Medical College Hospital,
Calcutta

ALTHOUGH acute lobar pneumonia is a common malady, infection of the peritoneum is an uncommon occurrence. It is also very curious that both the pleural and the pia-arachnoid membranes are frequently involved in acute pneumococcal infection but the peritoneum is seldom found to be the site of disease. In the study of acute lobar pneumonia, peritonitis is always cited as a complication but in actual fact the latter condition is rarely seen either clinically or in the autopsy room. In very severe cases of lobar pneumonia, it is often found that the abdomen becomes enormously distended giving rise to some pain, tenderness, diarrhoea or constipation, and even obliteration of the liver dullness in front. Such a picture gives rise to a suspicion of involvement of the peritoneal sac, but this has not been corroborated on the autopsy table. The literature on the subject is very scanty, Barrington-Ward found only 20 cases in 15 years in the hospital for sick children at Great Ormond Street. Duncan has reported only 34 instances during the period of 10 years in the Children's Hospital at Toronto. Obadolek has observed 50 cases in 10 years in his clinic at Brünn. Indian statistics are notoriously scanty and the writers have not yet found any well-authenticated series published anywhere. Under such circumstances discussion of the subject with the illustration of a case may be of interest.

Case report

N. S., 11½ years, Hindu male, was admitted into the Medical College Hospitals on 9th April, 1940, with the following complaints:

Pain in the abdomen and gradual swelling for the last 25 days; dyspnoea for the last 7 days; swelling of the legs for the last 3 days.

History of the present complaint.—On the morning of 11th March, after taking his bath, the patient had a sudden rise of temperature accompanied by chill

and rigor. The fever rose to 103°F , but it came down to 100°F . next morning. The temperature continued for 8 days but dropped to normal on the morning of the 9th day of the illness, although it rose again in the evening. An intermittent temperature continued till the date of his admission into the hospital on 9th April.

On 13th March the patient had passed several loose motions but on the next day he complained of constipation and pain in his abdomen. Also he did not pass any urine. On the 5th day of his illness he was given an enema after which his bowels became irregular and he suffered from alternate constipation and diarrhea. He also noticed that his abdomen was gradually becoming distended. The patient became breathless for the last 7 days and he noticed swelling of the feet and legs 3 days prior to his admission into the hospital.

Past history.—The patient had suffered from osteomyelitis of the right tibia at the age of one year.

Family history.—The patient is the fourth issue of his parents. He has three brothers and three sisters all of whom are healthy. Before the onset of his illness, the patient was the healthiest of all.

Physical examination.—Marked emaciation, dyspnoea and anaemia; no jaundice; no glandular enlargement; abdomen markedly distended; œdema of legs and scrotum; tongue moist and coated; temperature 99.4°F ; pulse 104; respiration 42; dyspnoea; cough present but not troublesome; marked diminution of movement on the right side. Vocal fremitus markedly impaired at the axillary, infra-axillary and infra-scapular areas on the right side and there was stony dullness over them. On auscultation, breath sounds were found to be absent over the above areas. On the left side, signs of consolidation were detected. Apical impulse was found in the left fourth intercostal space. The heart sounds were weak and a haemur murmur was heard over the mitral and pulmonary areas. The abdomen was distended. Fluid thrill and shifting dullness were present. There were a few prominent veins on the abdominal wall filling from below upwards. The liver and spleen could not be palpated due to distension. Urine was very scanty.

Laboratory findings.—Blood: Haemoglobin 50 per cent; red cells 2,650,000 per c.mm.; leucocytes 18,750 per c.mm.; polymorphonuclears 90 per cent; lymphocytes 8 per cent; monocytes 1 per cent; eosinophils 1 per cent. No malarial parasites found. Blood culture—negative. Agglutination test—negative to T.A.B.

Urine: Yellow colour. Specific gravity 1020. No albumin or sugar. Plenty of phosphates. The sediments contained a few pus cells but no red cells nor casts.

Subsequent progress of the case.—After his admission into the hospital, appropriate treatment was started but as the dyspnoea did not improve, the right pleural cavity was aspirated on 13th April and 8 ounces of greenish coloured pus was taken out. Bacteriological examination revealed the presence of pneumococci in large numbers. On the next day, paracentesis of the abdomen was done and 42 ounces of pus of a similar nature was withdrawn. Bacteriological examination showed a pure growth of pneumococcus. When the distension was relieved a fairly big mass, apparently loculated pus, could be felt in the right hypochondriac region. As the abdomen filled up again, a second paracentesis was performed and 48 ounces of similar pus withdrawn from the peritoneal cavity. This improved the general condition of the patient and brought down the temperature to 99.5°F . Now the peritoneal cavity was drained by closed drain method through a supra-pubic incision, and several pints of pus came out in the course of a week. The mass in the right hypochondriac region disappeared and the patient slowly and steadily made an uneventful recovery. Of course throughout the period of his stay in the hospital, appropriate medical treatment including administrations of sulphapyridine and injections of pneumococcal immunogen were given

to the patient. He was discharged from the hospital on 17th June as a healthy robust child.

From a study of the above case record it will be seen that the boy got an attack of generalized pneumococcal infection which affected his lungs as well as his pleural and peritoneal membranes. Somehow or other, he managed to put forth an adequate immunity to localize the organisms which finally settled in the serous membranes giving rise to a suppurative inflammatory process. The amount of exudate in the peritoneal cavity became very considerable and hence the distension was also very marked. Although the immunity was just sufficient to localize the infective elements, it was not adequate to cause their death and lysis and hence the pneumonic changes in the lungs failed to undergo complete resolution and was found in a state of delayed resolution. This latter however cleared up completely when the necessary treatment was started to kill the pneumococci and remove their exudate from the pleural and peritoneal cavity. The presence of diarrhoea at the outset and the irregular bowel action during the subsequent period of the illness may be noted. The combination of pneumococcal peritonitis with empyema on one side and unresolved pneumonia on the other is extremely rare.

Pneumococcal peritonitis is a disease of children and its incidence is undoubtedly greater in the female sex. A primary infection of the peritoneum is extremely rare. Usually it is secondary to an infection in some other part of the body. Owing to its preponderance in the female sex, it has been suggested that the organisms spread through the genital tracts. But this is very difficult to believe when we find that the disease also occurs in a fairly large proportion of boys. Besides, bacteriological examination of the genital canal of girls often proves negative. An investigation of this nature carried out by Dr. Nabarro, pathologist to the children's hospital at Great Ormond Street, amongst London children proved conclusively that pneumococci were not always found in their vaginal discharge. It is now a universally accepted belief that the organisms reach the peritoneum via the blood stream from a primary focus in some part of the respiratory passage. A severe sore throat, tonsillitis, otitis media, acute laryngitis, pneumonia, and broncho-pneumonia may serve as a focus from which showers of pneumococci are discharged into the blood stream and in the absence of an adequate defensive reaction they may lodge anywhere in the body and start their morbid changes. In this way, the occurrence of serous membrane involvement can be easily explained. But what is more difficult of explanation is the fact that it occurs almost exclusively in children. Whether it is the defensive architecture which is naturally immature or a special predilection brought about by an as-yet-unknown factor still remains to be explained.

Diagnosis

The clinical picture of pneumococcal peritonitis is fairly characteristic in many instances. The most important thing is that one must always keep an open mind regarding the existence of such a condition. The illness may begin with overwhelming suddenness but more usually there are 2 or 3 days of indefinite fever, malaise and catarrh of the upper respiratory tracts. Vomiting, diarrhoea and abdominal pain may be very early as in the case mentioned. The temperature is usually high and the pulse and respiration are much increased. The abdominal pain is not of a colicky nature but more or less diffuse and constant. This is soon followed by distension, rigidity and tenderness all over the abdomen. If there is a concomitant involvement of the lung or pleura pneumococcal infection is suggested. If on the other hand no lung signs develop, one is liable to make a diagnosis of general peritonitis due to acute appendicitis. A definite diagnosis at this stage is wellnigh impossible. A careful history, colicky nature of the pain which is more central in the beginning, maximum tenderness in the right iliac region and a board-like rigidity are however some of the features which may suggest acute appendicitis. In pneumococcal condition, the abdomen has a doughy feel, the face is flushed, the skin is hot and burning, the respiration hurried and there may be cyanosis. Herpes may be present. Besides acute appendicitis, the condition may be confused with septicæmia and peritonitis due to infection with haemolytic streptococci. This confusion is worse when the intensity of toxæmia is very great and the infection overwhelming. The diagnosis, in such instances, can be settled either by laparotomy, or on the autopsy table. When the condition is of long standing and is not associated with much toxæmia, the suggestion of tuberculous peritonitis is very strong. Signs and symptoms of tuberculous toxæmia such as rapid loss of weight, marked sweating, troublesome dyspepsia, and diarrhea with large pale frothy evacuations would be wanting, whereas a high leucocyte count with increased percentage of polymorphonuclear neutrophils would be definitely against it. Signs of consolidation in the lung and effusion into the pleural cavity helped us in our diagnosis of the case under review, as the fluid withdrawn from the right pleural cavity revealed the infecting organisms.

Prognosis

Next to tuberculous peritonitis, this condition has the most favourable outlook. A good deal depends on the mode of infection, i.e., whether it is an acute diffuse infection, acute infection passing into a subacute or chronic phase or early localization into the peritoneal cavity with formation of big collection of pus. In the last two conditions the prognosis is favourable and if appropriate treatment is instituted, recovery takes place. But in the first condition which is

a part of a septicæmia, recovery is rare. Other factors which determine the ultimate recovery are the presence of a co-existent pneumonia, involvement of other serous membranes such as the pleura, pericardium and the meninges and the existence of devitalizing constitutional diseases, such as Bright's disease, diabetes, and chronic splenomegalic conditions. In these days, the outlook has also been considerably modified by the discovery of new and powerful chemotherapeutic drugs.

Treatment

This is a fairly simple matter when the infection has localized and pus formation has taken place. Simple drainage with treatment of the infection in other parts, such as the lungs and the pleural cavities, will clear up the condition in the majority of cases. But it is in the early diffuse type with overwhelming infection that the problem of treatment is very unsettled. This condition is a blood-borne infection and is a manifestation of septicæmia with a diffuse peritonitis leading to matted coils of intestine and collections of pus shut off from the general cavity. Obviously drainage cannot be effective in such a condition. Moreover, a major surgical operation on the peritoneal cavity may be just sufficient to cause a break-down of the last resistance of the child and determine a fatal issue. It is a matter of common experience that acute general peritonitis is a very fatal disease whatever may be the treatment. In such a malady, conservative treatment may be able to convert an acute into a chronic condition with residual abscess formation when the chances of cure would be much greater.

Under circumstances where a definite diagnosis cannot be made, one must always bear in mind that an acute gangrenous appendix may remain in the background and unless a quick surgical operation is performed, the result may be fatal. In such a case a quick laparotomy should be done under gas and oxygen to find out the condition inside the abdomen leaving a pelvic drainage.

If the amount of exudation be very large, as in the case reported, it is better to do one or two preliminary paracenteses before undertaking surgical drainage. At the same time all attempts should be made to mobilize the defensive forces of the body by adequate easily assimilable nourishing diet containing enough vitamins, sulphanilamides, and massive doses of iron and tonics.

The writers take this opportunity to acknowledge their sincere thanks to Lieut.-Colonel J. C. De, I.M.S., superintendent, Medical College Hospitals, for permission to publish the records of the case. Their thanks are also due to Dr. K. K. Ghose, resident surgeon, Medical College Hospitals, for his surgical assistance and to Prof. B. P. Tribedi for the bacteriological reports.

CHEMOTHERAPY IN THE TREATMENT OF CEREBROSPINAL MENINGITIS

By T. P. VARMA, M.B., D.T.M.

Medical Officer and Superintendent, Central Jail, Hazaribagh

NINE cases of cerebrospinal meningitis occurred in the Hazaribagh Central Jail, which has an average population of about 1,000, between the 1st April and 17th May, 1940, out of which three died and the rest recovered.

Chemotherapy.—M. & B. 693 and proseptasine with anti-meningococcal serum were tried in all except the two fulminating cases. As there was a shortage of M. & B. 693 which was obtained after some delay, proseptasine which was in stock was given to supplement the drug in four cases. The drugs were administered orally, being crushed and given as a suspension in water.

The number of cases treated is too small to warrant the drawing of conclusions, but lends additional support to the efficacy of the combined treatment with serum and sulphanilamide groups of drugs in reducing the mortality rate. In view of the fact that such treatment is comparatively a recent innovation the details of the cases are briefly recorded.

Details of the cases

Case 1.—Hindu male, aged 25 years, under-trial prisoner, admitted into jail on 21st March, 1940, was admitted into the jail hospital on the morning of 1st April, having had fever with rigor on the previous night; temperature on admission was 102°F. Blood film was negative for malarial parasites. On 2nd April the temperature came down to 97°F. and rose up to 100°F. in the evening. The same happened on 3rd April, but the patient was stuporous and had considerable neck rigidity and a bilateral positive Kernig sign. Lumbar puncture disclosed turbid cerebrospinal fluid under pressure.

Bacteriological report of the cerebrospinal fluid revealed microscopically Gram-negative intracellular diplococci, numerous pus cells and a few lymphocytes, on culture, sterile up to 72 hours' incubation in blood agar tubes heavily inoculated with the fluid.

The temperature range was low, between normal and 99°F. By the thirteenth day no sign of meningitis remained and his progress was good, he was free from pyrexia and cheerful and bright. His convalescence was uneventful and he was discharged from hospital on 1st May, but kept in convalescent gang. M. & B. 693 tablets with anti-meningococcal serum intrathecal and intravenous were given; details are shown in a separate table.

Case 2.—Hindu male, aged 20 years, under-trial prisoner, admitted into jail on 17th March, 1940, was received in the jail hospital in the evening of the 7th April, history of rigor, temperature 104°F., pulse rate 120, respiration 22, spleen palpable, no stiffness of neck, no Kernig sign, lungs clear. At about 4.30 a.m. he had convulsion and became comatose, and died two hours later at 6.30 a.m. on 8th April within twelve hours of admission. No lumbar puncture was done. Blood film was taken, no malarial parasites were found.

Post mortem—the meninges and brain were found intensely congested with deposit of fibrin. Ventricles and spinal canal were found dry, spleen 11½ oz., other organs deeply congested, otherwise healthy.

Treatment.—Cardiazol injection, intravenous glucose injections, and hydrotherapy.

Case 3.—Hindu male, aged 18 years, admitted into jail on 22nd April, 1940. Admitted into jail hospital on

1st May, temperature 104°F., pulse thready, respiration 40 per minute, no stiffness of neck, no Kernig sign, complained of headache and severe pain in the joints. At 5 p.m. the same day he became delirious, the next morning he became unconscious, no stiffness of neck, Kernig sign negative, pulse imperceptible, he died the same morning. Lumbar puncture revealed turbid cerebrospinal fluid under pressure; in a slide prepared from the fluid with methylene-blue, intra- and extra-cellular diplococci and numerous pus cells were found; unfortunately the ampoules containing the cerebrospinal fluid sent for bacteriological examination were broken during the transit.

Treatment.—Camphor in ether 1 c.c.m. every four hours subcutaneously, glucose solution (25 per cent) 25 c.c.m. intravenously, anti-meningococcal serum 20 c.c.m. intrathecally and M. & B. 693 tablets 3 grammes.

Case 4.—Hindu male, aged 46 years, convicted prisoner, admitted into jail on 24th December, 1939, was received in the jail hospital from a ward in the same block as under-trial ward on the morning of 1st May, 1940. Temperature on admission 101°F., pulse rate 116, respiration 26, intense headache, no stiffness of neck, no Kernig sign. The next morning he was very irritable, stiffness of neck was present, and Kernig sign positive. Lumbar puncture revealed turbid cerebrospinal fluid under pressure. The ampoule containing cerebrospinal fluid sent for the bacteriological examination with that of case 3 was broken during transit, microscopically diplococci, and pus cells found.

Treatment.—Anti-meningococcal serum was given both intrathecally and intravenously and also M. & B. 693 orally. The temperature came down to normal on 8th May and the meningeal sign disappeared and patient was quite conscious. But on the 10th May he died in the evening of acute respiratory failure.

Case 5.—Hindu male, aged 32 years, convicted prisoner, admitted into jail on 15th February, 1940, was received in the jail hospital on the morning of 1st May, 1940. Temperature 104°F., pulse rate 140, respiration 36, complained of severe headache, no stiffness of neck, no Kernig sign, spleen palpable. In the evening he was very restless, irritable and stuporose, and a few discrete red papules were noticed over the front of the chest and abdomen. On the 3rd May, 1940, stiffness of neck and Kernig sign positive, condition almost same as before. On 4th May slight improvement in the mental condition was noticed and temperature had come down to normal. On 5th May, 1940, the temperature again went up to 102°F., and on 6th May it was 103°F., but gradually came down till it was normal on 12th May, when convalescence set in, the meningeal signs had disappeared, and the patient's mental condition was normal. He was discharged from hospital on 4th June.

Treatment.—M. & B. 693 was given orally and anti-meningococcal serum intravenously.

Case 6.—Hindu male, aged 23 years, under-trial prisoner, admitted into jail on 21st February, 1940, was brought to the jail hospital on 4th May (morning), temperature 101°F., pulse rate 110, respiration 28, complained of severe headache. Spleen was palpable, no stiffness of neck, Kernig sign negative. In the afternoon he became unconscious and stiffness of neck and Kernig sign were positive. Lumbar puncture revealed turbid cerebrospinal fluid under great pressure. On 5th May temperature was 99.5°F. and it gradually came down to normal on 8th May, when the meningeal signs had disappeared and consciousness was regained. He was convalescent and was discharged on 23rd May. *Bacteriological report:* microscopical examination—meningococci, intracellular and extracellular, found and on culture meningococci were grown.

Treatment.—As the stock of M. & B. 693 had been nearly exhausted, prosepstasine tablets were also given orally to supplement it, with intravenous and intrathecical anti-meningococcal serum.

Case 7.—Hindu male, aged 30 years, under-trial prisoner, admitted into jail on 29th April, 1940. On 5th May he was admitted into the jail hospital with

temperature 101.5°F., pulse rate 108 and respiration 20. Spleen was palpable, no stiffness of neck, no Kernig sign, complained of headache. On the 6th he complained of very severe headache; stiffness of neck and Kernig sign were present and he had nausea. Lumbar puncture revealed turbid cerebrospinal fluid under pressure. *Diplococcus meningitidis* was grown on culture.

Treatment.—Intrathecal and intravenous anti-meningococcal serum and proseptasine and M. & B. 693 tablets were given orally. On the 12th, i.e., the 8th day of illness, the temperature was normal. He was discharged on 1st June, on the 28th day of his illness.

Case 8.—Hindu male, aged 30 years, convicted prisoner, admitted into jail on 4th January, 1940; he was admitted into jail hospital on 11th May with temperature 103.5°F., pulse 110, respiration 28, spleen palpable, stiffness of neck, and Kernig sign absent. Lumbar puncture revealed turbid cerebrospinal fluid under pressure. *Diplococcus meningitidis*, extracellular and intracellular, found in large numbers in the cerebrospinal fluid microscopically and also isolated on culture.

Treatment.—Anti-meningococcal serum was given intrathecally and intravenously and M. & B. 693 and proseptasine tablets orally. The temperature came down to normal on the sixth day of the disease and continued so till his discharge from hospital on the 4th June.

Case 9.—Hindu male, aged 35 years, admitted into jail on 17th March, 1940. On 17th May he was admitted into jail hospital with temperature 102.5°F., pulse

Hazaribagh Central Jail during April and May 1940. Four of these were fully authenticated meningococcal meningitis and in three, including the first case in which culture was negative, microscopical examination revealed diplococci. Of the remaining two one was a case of fulminating type being fatal within 12 hours, and in the other no cerebrospinal fluid could be withdrawn on lumbar puncture.

Excluding two fulminating cases, seven of these cases were treated with the sulphanilamide group of drugs, M. & B. 693 and proseptasine, a single spinal drainage and a single dose of intrathecal polyvalent serum (Bengal Immunity Co.) except in one case, and intravenous serum, with only one death.

Striking clinical improvement was noticed within three or four days of the commencement of treatment.

I take this opportunity of thanking Lieut.-Colonel A. N. Bose, I.M.S., Bacteriologist to the Government of Bihar, for kindly examining the specimens of cerebrospinal fluid submitted to him.

Table showing treatment and result

Case number	AMOUNT OF SERUM GIVEN IN C.C.M.		AMOUNT OF DRUG IN GRAMMES			Result	Actual period of illness in days	BACTERIOLOGICAL EXAMINATION OF C. S. FLUID	
	I. T.	I. V.	M. & B. 693	Proseptasine	Total			Smear	Culture
1	10	30	16.5	Nil	16.5	Cured	13	+	-
2	Nil	Nil	Nil	Nil	Nil	Died	‡
3	20	Nil	3	Nil	Nil	"	1	-	..
4	20	50	18	Nil	18	Died (acute respiratory failure).	10	-	..
5	Nil	80	16	Nil	16	Cured	12
6	10	40	6	25	31	"	5	+	+
7	10	70	15	26	41	"	8	+	+
8	10	75	12	13	25	"	6	+	+
9	10	50	6	10	16	"	5	+	+

rate 136 and respiration 40, slight headache, no stiffness of neck or Kernig sign present. Fine crepitant râles were heard over the base of the right lung. Lumbar puncture revealed turbid cerebrospinal fluid under pressure. Microscopically large number of pus cells and Gram-negative diplococci present; *Diplococcus meningitidis* was isolated on culture.

Treatment.—Anti-meningococcal serum intrathecally and intravenously and M. & B. 693 and proseptasine tablets were given orally. Temperature came down to normal on the second day of disease but there was a sharp rise to 102°F. on the fourth day with a drop to normal the next day; his temperature was normal till his discharge on the 4th June.

Summary

Nine cases of cerebrospinal meningitis were treated in the hospital attached to the

I am also grateful to Lieut.-Colonel O. R. Unger, I.M.S., Inspector-General of Prisons, Bihar, for his kind permission to publish the cases.

KANGRI-BURN CANCER

By ERNEST F. NEVE, M.D., F.R.C.S. (Eng.),
F.R.C.S. (Edin.)*

Consulting Surgeon, Kashmir Mission Hospital

How strange it seems that an earthenware bowl, basket covered and surmounted by a wicker handle, should be able, when held under a pheran against the body, to wreak such mischief. From the mouth of the bowl, under the handle, direct heat is given off from the glowing wood charcoal, but heat also passes through the walls of the kangri and the wicker work in which it is enclosed. I have tested the temperature to which the skin is exposed. *In situ* it ranges between 150° and 200°F. The wood charcoal, which is put into the kangri, is obtained from various sources—willow, witch hazel, chenar leaves, and sometimes pine-wood.

Aetiology.—The theory has been put forward that the cancer is due to chemical vapours given off by the charcoal. In support of this idea, the experiments with coal tar on rats and mice, and the chimney sweeps' cancer due to contact of soot with the skin have been adduced.

One thing is quite certain that *irritation* is a cause of cancer. It is common knowledge that any little innocent superficial growth, warty or otherwise, is in danger, especially in elderly people, of taking on malignant action, if it is perpetually rubbed, scratched or treated with caustics.

There is still one school of thought which believes cancer to be a parasitic disease due to some particular form of contagion. The cancer from which fowls suffer, and the interesting work of Barnard and Gye are quoted in support of this view. I think that it is quite evident that the Kashmir kangri-burn epithelioma is produced by heat apart from products of combustion and it is in no sense a parasitic disease due to micro-organisms.

I remember a case in the Edinburgh Royal Infirmary 60 years ago when I was a student, a man with a fungating ulcer on the front of the leg. He was under my care. The history was that his work was in a comb factory, and that his leg rested against a hot water pipe, in connection with which this ulcer had arisen, and increased. Looking back I can now see clearly that this was an epithelioma of the same type as the kangri-burn cancer. The surgeon in charge appeared in doubt, and wanted to take a small piece and examine it microscopically; the man objected and decamped.

The effect of heat, in my opinion, is evident. The epithelioma of the lip from smoking clay pipes, and now sometimes seen as the result of cigarette smoking. Cancer of the tongue may

be similarly produced; but any *chemical irritation* may have a similar action, as for instance in the *betel chewers' cancer*, so common in south India. The frequent application of coal tar in the experiments on rats, and the ensuing cancer is another case in point.

With regard to *kangri-burn* cancer I think that there can be little doubt that continued exposure to heat, going on over long periods, beginning perhaps in childhood and extending over adult life to old age is the exciting cause. Very often, at one time or another, there has been a severe burn, with a resulting scar. Such scars are peculiarly liable to be attacked. The cancer does not, however, usually develop until middle or old age. The average age indeed of those coming under observation with this disease is between 50 and 60. Only about 7 per cent of the cases are in people over 70. *Kangri-burn* cancer is considerably more common in men than in women. This may perhaps be explained by the fact that the domestic occupations of women do not admit of very continuous use of the kangri. In connection with the difference in the sexes of liability to certain types of cancer, I have been told that in China the men are much more liable to carcinoma of the stomach than the women, and the alleged reason was that the men eat their rice very hot, whereas the women have to wait until the men have finished, by which time the rice is no longer hot.

Nature of the growths.—Many elderly Kashmiris exhibit small localized papules or macules on the skin, with a tendency to epithelial overgrowth. These may be found on any part of the body, even those not exposed to heat irritation. They are however more abundant on sites exposed to the direct action of the kangri. It is just possible that irritation owing to heat applied in one area may stimulate epithelial growth elsewhere. Certainly at the seats of election of the cancer, the anterior surface of the abdomen above or below the umbilicus, the epigastric region, and even sometimes the lower part of the front of the chest, also often the inner sides of the thighs, the little epithelial plaques are found in varying stages of development from simple papules with a scaly surface, or raised warty areas or horns sometimes reaching an inch in length, up to the actual squamous epithelial cancer. Owing to the constant application of heat, the skin of the abdomen or inner aspect of the thighs is apt to appear dry and parchment-like. The course of the superficial veins may be mapped out by brown pigmentation. Every degree of chronic dermatitis may be met with, from mere redness, with or without desquamation, to actual scars, the result of destructive burns. These scars are especially liable to become the starting points of malignant action. Thus we have, under observation, in different patients, every stage from the earliest signs of epithelial proliferation to the most advanced cancerous growths

* We regret that we did not receive this contribution in time for our 75th anniversary number. Dr. Neve must be our oldest active contributor; his first contribution on 'The Evolution of Antiseptic Surgery; a Retrospect' appeared in the June number, 1893.—EDITOR, I. M. G.

with secondary deposits in neighbouring lymph nodes.

The lesion starts at the surface. It is a local disease from a local cause. It is never found on the back or extensor surfaces of the arms, but the anterior aspect of the thighs may sometimes be affected. The hands, face and feet enjoy immunity.

The evidence of the kangri-burn cancer is indeed strongly against the parasitic theory of the origin of cancer. It is noteworthy that the disease is apt to supervene at the period of life, when active, vigorous growth and development are slowing down, or have ceased, and when the endocrines which act as stimulants and controlling agents are no longer powerful.

Histology.—In the early stages of the kangri-burn cancer, ulceration is absent, and the growth consists of a mere warty thickening of the skin. Examined microscopically, the epidermis is seen to be much thickened, and underlying it an infiltration of new epithelial cells can be demonstrated tending to obliterate the papillæ. In a more advanced stage a breach of continuity is seen to have taken place in the surface and there is an ulcer with a ragged floor, the papillæ are hypertrophied, the nuclei of the stratum granulosum are prominent and sharply defined, and the cells of the corium are actively proliferating. There are some cell nests, and numerous minute blood vessels without unstriated muscle.

Gross pathology.—Macroscopically, there are three common forms of this cancer. The commonest is an ulcer more or less circular or oval, about an inch and a half in diameter, with raised irregular edges and deep crater-like centre. Sometimes part of the tumour is fungating and in other parts there are deep pockets.

The second form, which is less common, is a growth consisting of a cauliflower-like excrescence, which may project one or two inches from the surface and measure two to three inches across.

The third form is met with in those of more advanced years. Here there is little apparent over-growth, but small or large ulcerated areas with irregular steep edges, in places undermined, and a rugged floor rendered uneven by deep recesses.

These cancers, when ulcerated, are always very foul and the skin is sodden with septic discharge, which dries and becomes adherent at the margins and to some extent on the surface of the growth.

Glandular infection.—Lymph nodes become infected fairly soon, especially where the stage of ulceration has been reached. In the thigh, not only are those along the saphenous vein and in Scarpa's triangle involved, but, in advanced cases, the deep femoral and external iliac and inguinal lymph nodes near the pubis are also affected, especially the external pubic. In lesions of the abdominal wall, if below the umbilicus, the external iliac and inguinal

lymph nodes are attacked; if above the umbilicus, the anterior axillary lymph glands may be involved, or even deep glands beside the axillary vessels, and occasionally the sub-scapular glands. Not infrequently small enlarged lymph nodes are found across the side of the chest between the epigastrium and the axilla; this is however quite exceptional.

In advanced cases the infected glands may attain the size of a pigeon's egg, and they may become mere bags of soft epithelial debris, very septic if ulceration has occurred. When these nodes break down the result is absolute disaster. Diffuse infiltration occurs, the overlying skin becomes red and brawny, and suppuration persists.

Under these conditions the secondary deposit presents an appearance more or less approximating to that of the primary growth, except that the ulcer is deeper and the discharge more abundant and foul.

After months or possibly years of suffering, the patient dies of exhaustion, septic intoxication, or from haemorrhage, for sometimes the femoral or axillary artery may be opened into by ulceration.

The malignancy of these epitheliomata does not seem to be great. We often obtain a history of from one to five years' duration, sometimes much longer. More than 50 per cent of the cases show secondary infection when first seen by us.

Hospital statistics.—During fifty years, 3,064 operations were performed in the Kashmir Mission Hospital for kangri-burn epithelioma; 44 deaths occurred after operation, or rather over 1.3 per cent. It must however be remembered that in some cases there was recurrence and in others infected lymph nodes, undiscovered at the time of operation, may have developed.

The nature of the operation.—This is a very important point. Where, as is usually the case, there are enlarged lymph nodes these should first be dealt with and they require very careful handling to avoid rupture and possible wound infection from their contents which may also be septic. Small glands are very apt to escape notice, especially the external pubic group. In order to avoid septic contamination of the operation wounds before proceeding to the removal of the primary tumour, very great and thorough care must be taken in cleansing the surrounding skin, with oil of turpentine, following it up with 1/500 mercury iodide spirit lotion. The great technical difficulty is to prevent contamination from the fungating growth itself during the operation. Sometimes the actual cautery is used to sterilize the surface of this. Sometimes it can be secured in double cyanide gauze as an additional precaution, or it can be subjected to a few days' preliminary treatment with chloride of zinc, 40 grains to the ounce. Then comes the test of operative skill. There is a knack in excising the primary growth.

With the aid of three or four volsella fixed in the skin around and well beyond the tumour and held well up by an assistant, the tumour is excised by a rapid clean incision, most carefully avoiding contaminating contact with the dangerous septic growth in such close proximity. Sometimes underlying muscle needs removal and occasionally small areas of peritoneum. In the latter case it is essential to ensure subsequent sound approximation of edges without tension.

With regard to infected lymph nodes, ill-defined induration and redness of surrounding skin is a contraindication to operation. Sometimes it may be worth while to excise the primary growth, even if the glands are inoperable.

In very bad cases in which, after operation, in spite of every precaution the wound becomes septic, Carrel's irrigation with 0.5 per cent hypochlorite is very effective.

Recurrences.—Many cases, when first seen, are really too advanced for surgical treatment. Others, returning to their homes after operation, disregarding the serious warning which they have received, continue to use the kangri, and, if they come back for treatment, it is difficult to say whether the recurrence which sometimes follows is the result of an incomplete operation or whether fresh neoplastic formation has been provoked by the continuance of the original irritant. If the lymph nodes are affected, in such returning cases, and the recurrent growth quite small, it is probably due to incomplete operation, some of the previously infected glands having escaped removal.

So far as we have been able to ascertain end results, we are of opinion that the proportion of recurrent cases is less than 20 per cent. Where lymph nodes are affected, experience has shown that it is not necessary to perform such extensive and drastic operations as those often necessary for carcinoma, for instance, of the breast. The malignancy of the kangri-burn epithelioma is not great, the actual lymphatic vessels appear to escape the infection which is transmitted to the nodes, and, if early operation is resorted to, the distribution of the lymph nodes remembered, and careful examination resorted to, the proportion of cases of complete recovery is much higher than after operations for carcinoma or sarcoma.

Conclusion

To sum up, the special importance of the kangri-burn cancer is the relation which it bears to the causation of cancer. Here is the case of a growth arising from a definite physical irritant, namely, heat rays. This places it in the same group as those produced by, for instance, x-rays and other physical or chemical irritants. It would appear that this direct irritation starts epithelial proliferation. The waning influence of endocrine balance, which becomes more marked in elderly people, and the loss of a

NON-SPECIFIC INFLAMMATION OF THE LUNG

By R. VISWANATHAN, B.A., M.D.,
M.R.C.P. (Lond.), T.B.D.

Lecturer in Tuberculosis, Medical College, Vizagapatam

ROUTINE radiographic examination of the lungs of patients attending a well-run chest clinic leads to the discovery, in some, of transient opacities in the lung fields, unaccompanied by the recognized symptoms of the classical types of pneumonia. Maxwell (1938), Gill (1938), Allen (1936) and others have given the name pneumonitis to a variety of these opacities. Ramsay and Scadding (1939) have analysed 21 cases with circumscribed shadows in the radiogram of the lungs. They criticize the nomenclature pneumonitis as applied to these lesions and suggest 'benign circumscribed pneumonia' as a more precise description. The writer has come across 11 such cases with localized opacities in the lung fields two of whom were treated as in-patients while the remaining nine attended the out-patients' lung clinic attached to the King George Hospital, Vizagapatam.

The age incidence varied from 5 to 46 years. Three were between 5 and 8, one was 12, and the remaining were above 15.

Out of the 11 cases only three were females.

Four patients gave previous history of asthma of duration varying from six months to two years. Two had suffered from recurrent colds followed by tracheo-bronchitis. The remaining had no previous respiratory troubles.

Only in three cases the onset was sudden with high fever. All the remaining eight patients sought advice in the clinic for slight cough and fever of varying duration not exceeding four weeks.

Cough was the presenting symptom in all the cases but one. Fever was present in all. But the degree of fever was very variable. In the two cases which were treated as in-patients the temperature remained high and continuous for the first 15 days or so after which period the fever came down by lysis. With only one single exception cough was associated with expectoration in all. In none of them was the

(Continued from previous column)

measure of trophic nerve control, allows these epithelial elements to escape regulation and form new growths.

This exact aetiology is of course speculative. For we know so little about the precise details of the control of growth, of the skin for instance. On a healing granulating surface we put a Thiersch skin graft or use Reverdin's method; that skin grows. Why does it stop growing when it has filled its needed space?

The one point about the kangri-burn squamous epithelioma is that its exciting cause is demonstrable and that parasitic origin appears to be most improbable.

Fig. 6. Case 3.

sputum blood stained. Most of the patients complained of lassitude, loss of weight and loss of appetite. The period of disease varied from two to eight weeks. The symptoms subsided one or two days earlier than the disappearance of the lung shadows in the radiographs.

Physical signs were very variable. No abnormal signs could be found in three cases. In four cases localizing signs, such as impaired resonance and few moist sounds could be elicited. In one case all the typical signs of localized consolidation were found. Three cases showed signs of bronchiitis only.

Radiographs showed circumscribed opacities of more or less uniform density in practically all cases. They varied in size from that of an anna-picce to that of an orange. All but one were situated in the lower lobe.

Discussion.—The interest in these cases is stimulated by the fact that their symptoms simulate those of active tuberculosis. Even the radiographic opacities may be mistaken for tuberculous caseating patches or specific allergic reactions in the lung going by the name epi-tuberculosis. Tuberculosis can easily be ruled out in these cases by the absence of tubercle bacilli in the sputum and the complete disappearance of the shadows in a comparatively short time.

Janneret and Famé (1933) have reported some very transient radiographic opacities observed in the course of routine examination in both normal subjects and patients with pulmonary tuberculosis without any symptoms whatsoever. They attributed them tentatively to atelectasis without supervening infection. That the cases in the present series had no atelectasis was shown by the rounded shape of the radiographic shadows and by the absence of mediastinal shifting even in those with large opacities.

The question that naturally arises is about the nature and causation of such localized inflammation of the lung tissue, which differs so markedly in their clinical manifestations from the classical types of pneumonias. The classical work of Blake and Cecil (1920) has shown that the organisms penetrate the bronchial walls and spread by the perivascular, peribronchial and septal interstitial tissue. Sharpe and Blake (1930) and Fried (1933) have performed experiments in which pneumonias were produced as a specific response to endotracheal introduction of substances to which the animal has been rendered hypersensitive.

The other mode of production is by aspiration of infected material as shown in the experiments of Terrel, Robertson and Coggshall (1933). Amberson (1937) has emphasized the importance of aspiration of infected mucus as a cause of pneumonia. He showed that lipiodol introduced into the nose of a sleeping individual could be demonstrated in the alveoli. Ikeda (1937) has reported numerous instances of oil aspiration occurring after oily substances were

introduced into the pharynx. In the same way there is every possibility of excessive secretion of infected mucus in the course of respiratory catarrhal infections producing pneumonic consolidations in the lung. Even by this mechanism lobar consolidation can occur either by confluence of lobar aspiration foci or as a complication of a massive lobar collapse (Ramsay and Scadding, *loc. cit.*).

The mechanism of production of circumscribed pneumonic consolidation is a matter for conjecture as none of the cases had a fatal termination to make autopsy possible. The aspiration mechanism is however more probable because of the pre-existing catarrhal affections in many of the cases. The previous history of asthma in some cases suggests another possibility of local allergic reaction in the lung.

No doubt these cases of benign circumscribed inflammations of the lung form a separate group because of their distinctly benign course, irregularity of symptoms and signs, and the variable duration of the affection. But are we justified in grouping them together as a separate clinical entity? The differences in the clinical manifestations of the three forms of inflammatory reaction of cellular tissue, namely, non-suppurative inflammation, abscess and cellulitis are only due to the difference in the virulence of the infecting organism and the resistance of the host. A close analogy can be drawn between the three inflammatory reactions in cellular tissue and the three types of inflammation in the lung tissue, namely, circumscribed pneumonia, abscess of the lung and acute lobar consolidation. Are we not justified in surmising that these different inflammations differ only in degree and that the differences in the clinical manifestations depend only on the virulence of the organism and the resistance of the host? The possibility of localized pneumonitis as being the cause of idiopathic abscess of the lung has been suggested by the writer (1939). But as the prognosis in the various forms of inflammation of the lung differ very markedly indeed it would be advisable to recognize them as separate groups though the essential pathogenesis in all the forms may be the same.

Case notes

Case 1.—Hindu male, 24 years, history of irregular fever, cough and dull ache on the left side of the chest for ten days. The radiograph (figure 1) on admission shows the dense opacity at the left base. Another (figure 2), two weeks later, shows almost complete clearing up of the opacity.

Sputum.—No tubercle bacilli were found. Culture showed pneumococci and streptococci.

Case 2.—Hindu male, 20 years, history of fever in the evening for 20 days, and dry cough for seven days. No pain. The radiograph (figure 3) on admission shows a dense opacity at the right cardiohepatic angle; figure 4, 16 days later, showing complete clearance.

Case 3.—Hindu female, 14 years, history of fever in the evening, cough with slight expectoration of six weeks' duration. Mantoux test negative. Sputum negative for tubercle bacilli. Culture showed pneumococci and haemolytic streptococci. Treated with

A PRELIMINARY STUDY OF PLAGUE AT
A HILL STATION IN THE NILGIRIS,
SOUTH INDIA

By P. V. GEORGE, B.A., L.M.S. (Madras), B.S.Sc.,
M.P.H. (Hopkins)
Research Officer
(Public Health Department, Madras)

and

B. TIMOTHY, M.R.C.S. (Eng.), L.R.C.P. (Lond.)
(King Institute of Preventive Medicine, Guindy,
Madras)

THE Nilgiris district has long been recognized as a potential plague zone. Potato farming is extensive in the whole district and in recent years it has become increasingly popular even as a cottage industry near the towns of Ootacamund and Coonoor. That field rats abound in potato farms is common knowledge. The health-conscious public of these towns have been, of late, much concerned with this problem of potato cultivation *vis-à-vis* plague, and attempted to discourage potato farming around residential areas by municipal legislation. The matter thus came to the notice of Government who ordered an enquiry into this matter to be made. The enquiry was accordingly carried out during the period May to July 1939, facilities for work being provided at the Pasteur Institute, Coonoor. The scientific aspects of this enquiry are included in this report. Field studies on plague undertaken in recent years at the instance of the Government and the Indian Research Fund Association in this province have all been connected with factors prevailing in the plains. The present enquiry has therefore contributed certain preliminary data pertaining to the epidemiology of plague in a hill station.

The Nilgiris is a plateau in South India, the smallest in extent and population of all districts in Madras province. It is roughly 1,000 square miles in extent upheaved at the junction of the

Eastern and Western Ghats, and has a population of about 170,000. The plateau has an average altitude of 6,500 feet though some of its peaks are over 8,000 feet high. The attached map shows the topography, and main routes of communication of the district. Over half the area is either forest or downs, a third is cultivated, and the rest is sparsely populated. The fertile areas in the district are chiefly composed of a rich black loam of a peaty nature. A brown soil comes next in value while other soils of inferior quality are chiefly used as grazing grounds. Of the lands utilized for agricultural purposes, less than half is cultivated with cereal crops, such as rice, wheat, *ragi*, *samai*, and barley, and over half with coffee, tea, cinchona, potato, etc. No portion of the district is irrigated. The grain grown in the district is hardly sufficient for 4 months' consumption in the year, and therefore much of these are imported either from Mysore and Malabar, *via* Gudalur, or from Coimbatore *via* the ghat road and the rack railway. Potato farming is very extensive, even as a cottage industry within the towns.

Climate.—The Nilgiris, owing to its high altitude, has one of the most temperate and equable of climates. Thus, for Ootacamund the average minimum temperature for the warmest month (April) is only about 9° higher than that for the coolest month (January) and the maxima for the same months vary only about 7°. Chart 1 shows the average monthly meteorological record for Ootacamund and chart 2 shows the average monthly plague death rate per mille of estimated population for the district for 35 years ending 1939. The annual rainfall averages about 67 inches, though it varies widely within the district from nearly 162 inches at Devala to about 56 inches in Ootacamund, depending on the effects of the south-west monsoon in each place. The humidity is low during the first 5 months of the year, and comparatively high during the remaining months. It has not been possible to procure necessary data for calculating average figures for saturation deficiency.

Plague in the Nilgiris

Plague first occurred in this district in Gudalur taluk about January 1903, and in Ootacamund in June of the same year. The disease then spread widely and rapidly all over the district and has been endemic ever since. The incidence of the disease has, however, been steadily coming down from the peak reached in the earlier years, though even with this decline a rough 3 to 4-year periodicity is evident, *vide* chart 3.

A special feature of the general incidence of plague in this district is, as stated in the geographical survey of plague in the Madras Presidency by Colonel Russell, that the usual difference between summer and winter months is not so clearly marked as in other districts (*vide* chart 2). This point is discussed later.

Another feature is that, unlike what now occurs generally in other districts, the urban

areas of Ootacamund and Coonoor, comprising only about a fiftieth of the total area of the

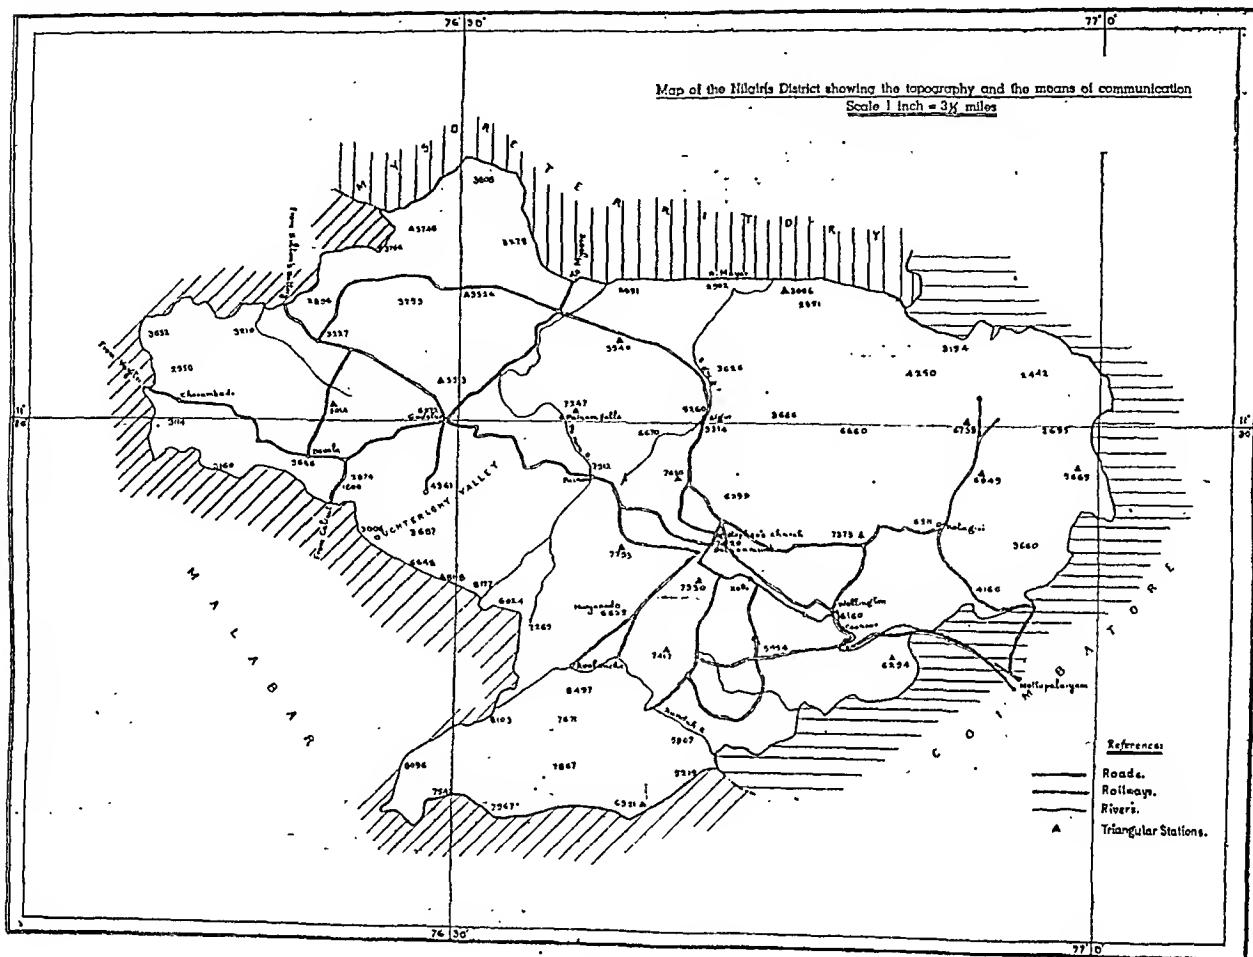

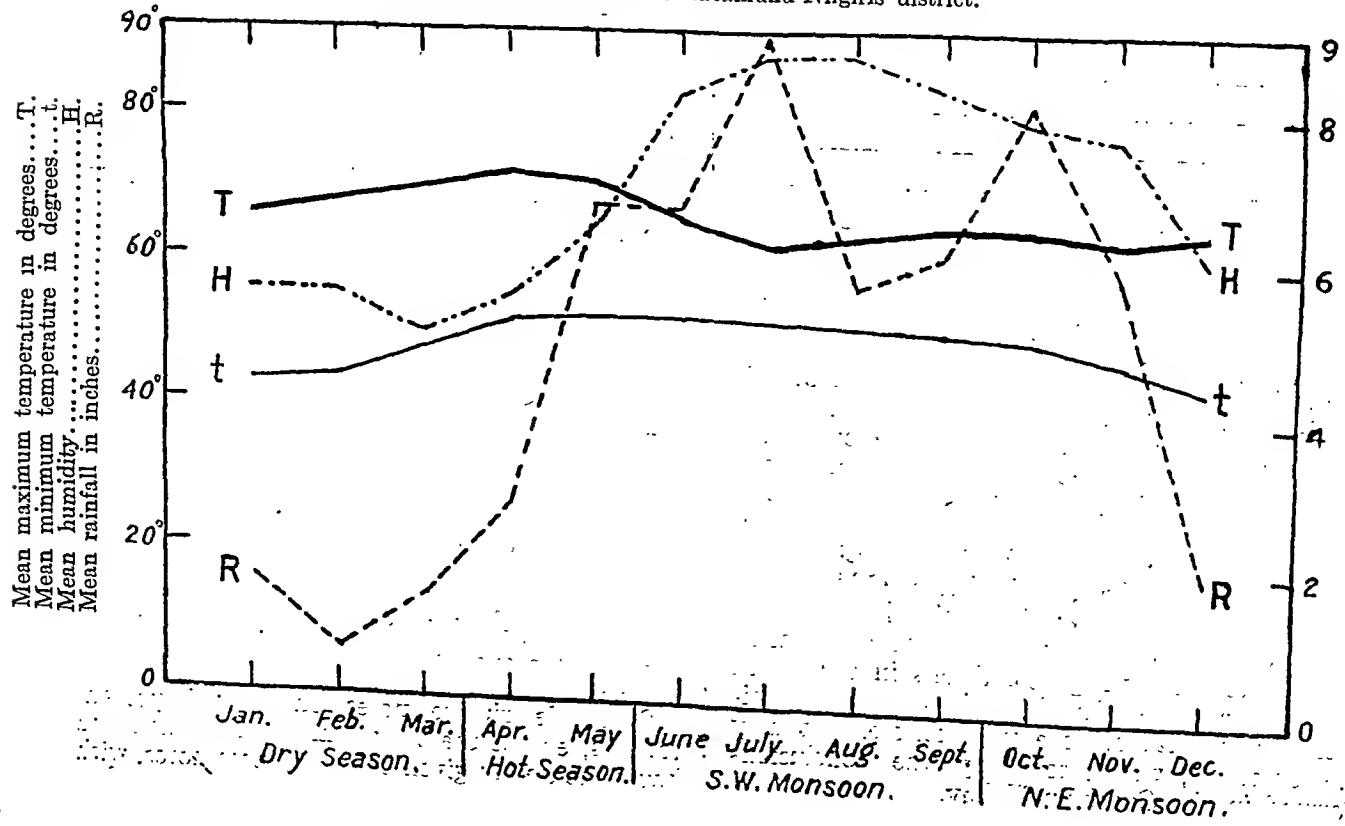

CHART 1
Meteorological chart. Ootacamund-Nilgiris district.

district and a quarter of its population, have been responsible for over 50 per cent of its total plague incidence.

Pneumonic plague.—Cases of pneumonic plague have occurred in the district at irregular intervals. Colonel Hutchinson, quoted by Wu Lien Teh (1926), reviewing the 10-year period 1913 to 1922, has recorded four limited pneumonic outbreaks in the Nilgiris, stating that 24 out of the 94 cases recorded in the whole province occurred in this district.

The chief lines of study undertaken during this enquiry were :—

(1) Study of rodents and fleas prevailing in this district with special reference to wild rodents in relation to plague.

(2) Transmission experiments with *Stivalius* and *Ceratophyllus* fleas.

The material for the enquiry was collected from various parts of the district through the co-operation of the planters and the officers of

CHART 2

Average monthly plague death rates, 1905-1939. The Nilgiris district.

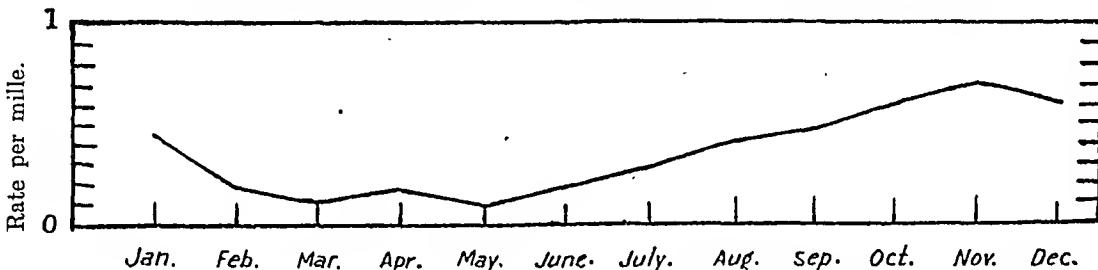

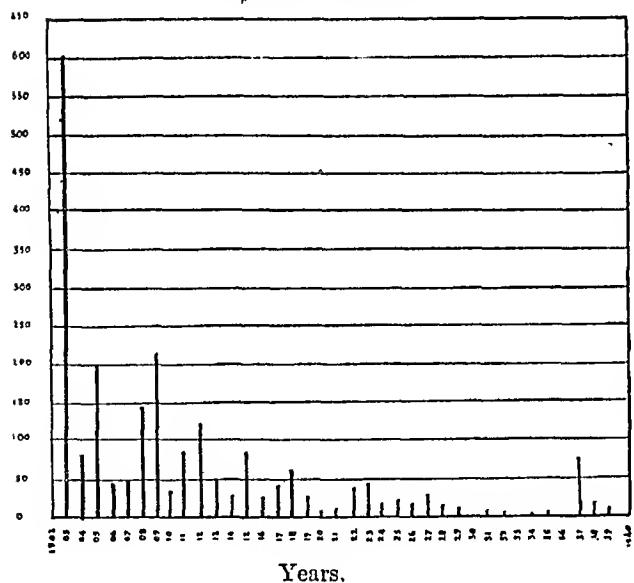

CHART 3

Deaths from plague in Nilgiris district during the years 1903-1939.

Sylvatic plague.—One of the purposes of this enquiry was to find out whether sylvatic plague actually existed now or whether the prevailing factors are favourable to its onset hereafter. Generally speaking, sylvatic plague does not seem to have interested plague workers in India. Studies in the Cumbum Valley, South India, reported by George and Webster (1934), and subsequent work show that sylvatic plague as such does not exist there. Cumbum Valley represents the average conditions in the plains of this province. In the Nilgiris where epidemiological factors are very different, it may be, after all, wrong to apply the conclusions formed in the Cumbum Valley.

the public health department of the district and by ourselves. The technique for field studies was mainly that adopted in the Cumbum Valley.

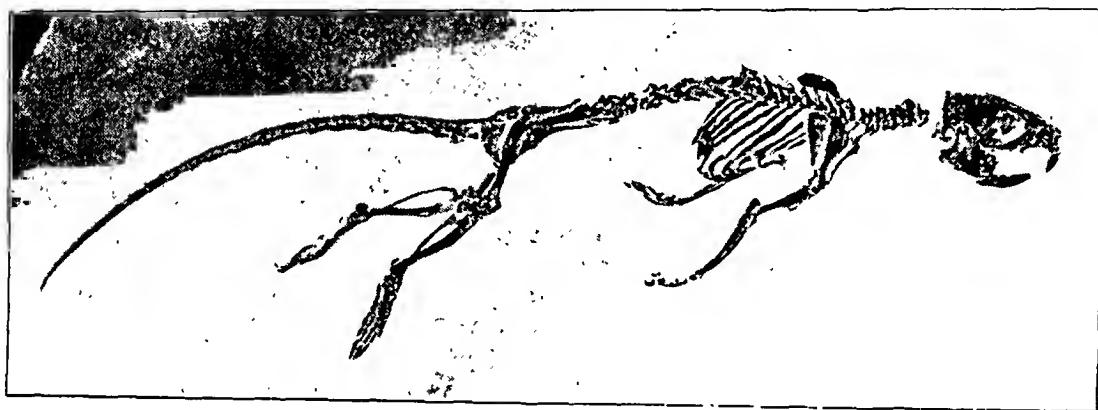

(1) *Rodents and fleas examined.*—One thousand and nineteen rodents comprising 556 house rats (*R. rattus*), 30 bandicoots (*B. malabarica*), 136 mole rats (*Gunomys kok*), 271 house mice (*Mus musculus*), 13 field mice (*Leggada booduga*), and 13 bush rats (*Golunda elliotti*), were obtained from various parts of the district for purposes of this enquiry. Seventeen musk rats (*P. ceruleus*) were also examined.

From rodents or their nests, 1,939 fleas were collected. These comprise *X. astia* (178), *X. brasiliensis* (514), *X. cheopis* (591), *Ceratophyllus nilgiriensis* (238), *Stivalius* sp. (387), *Leptopsylla musculi* (16), *Ctenocephalus* sp. (1) and *Pulex irritans* (14).

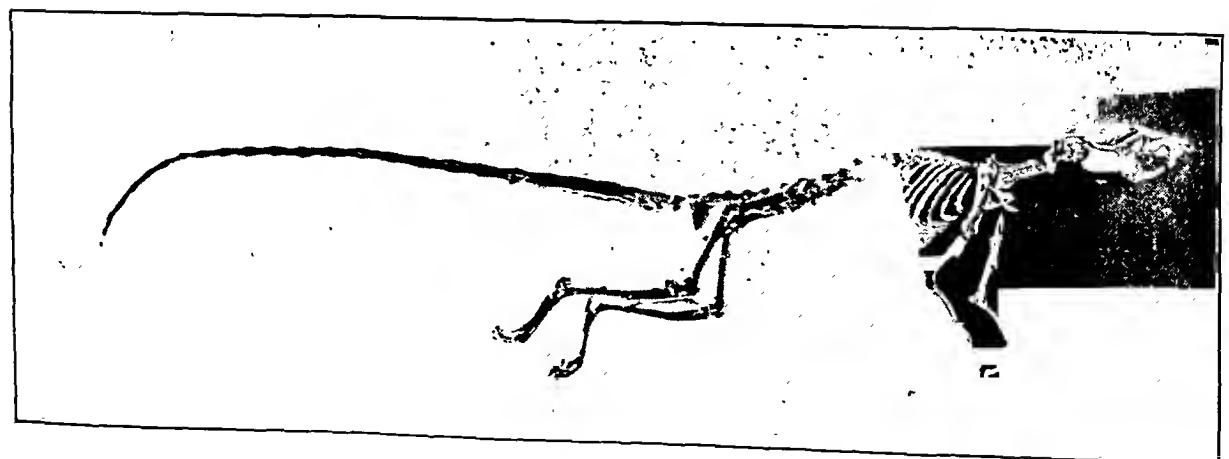

This list is not exhaustive as there are certain other rodents and fleas which were not obtainable. As the material was collected through various agencies, employing different methods, no attempt is made to estimate the species parasitic index of the fleas on the different rodents. It may be said that *R. rattus*, *B. malabarica* and *Gunomys kok* represent respectively the typical domestic, semi-domestic, and field species of rodents essentially concerned in the epidemiology of plague in the Nilgiris. While the rôle of the first two species may not be very different from what it is in the plains, that of the third is not clear, especially as it is found to harbour varieties of fleas not found in the plains.

Short descriptive notes on the important rodents, except the very familiar *R. rattus* and house mouse are given below. These notes, with

the accompanying photographs of the rodents and their skeletons, may be of interest to field workers on plague, *vide* plates V and VI.

Plates VII and VIII show the important features of the fleas referred to in the text, as seen through a hand lens.

Mole rats (*Gunomys kok* Gray).—The rodent which abounds largely in the cultivated fields both within and outside the municipal areas of the Nilgiris is the mole rat. One of its favourite habitats in this district is the potato farm, but it also prevails in uncultivated lawns, tea and coffee plantations, fruit gardens, etc. It is easily distinguished from other prevailing species by its big size, only excelled by the bandicoot, broad head, more or less bull-dog-like face due to unduly prominent masseter muscles, coarse dark-brown dorsal coat, short tapering tail with ill-defined annular rings and no tuft of hair at the tip, and, above all, by its characteristic grunt and ferocity. It burrows more deeply and extensively than many other rodents. While in the plains it lives mostly on the bunds of paddy fields and other damp environments, in this hill station it is found all over, even around human habitations. It actually seeks shelter in houses during rainy months, or when food is scarce outside. The burrows of mole rats are extensive with numerous intricate branches most of which are temporarily plugged with earth for protection against enemies. Fumigation of burrows with cyanide products, unless accompanied with necessary exploratory diggings to unplug them, has therefore only a limited success with mole rats, contrary to experience, with most other known plague rodents of South India. The nests of these mole rats usually contain, along with various bedding materials, large quantities of stored food. In the plains, often 4 to 6 lbs. of paddy or other grains are found in each system of burrows during the harvest season. In the nests in potato farms of the Nilgiris a number of potatoes are usually found.

One hundred and thirty-six mole rats and several of their nests were examined for fleas. It is interesting to note that 120 fleas collected from 5 mole rats and their nests at Nanjanad (7,400 feet altitude) were all *Ceratophyllus nilgiriensis*, while out of 230 fleas collected from 60 mole rats from the Pomological gardens in Coonoor (5,730 feet) 199 were *Stivalius* sp., 19 *Ceratophyllus nilgiriensis*, 11 *X. brasiliensis* and 1 *X. cheopis*. A rat flea survey by one of us (P. V. G.) of Ootacamund in 1929 revealed that while *X. cheopis* formed about 50 per cent of the fleas on *R. rattus*, they formed only about 8 per cent of the fleas on *Gunomys kok* within the town. At Coonoor, during the present enquiry, it was found that *X. cheopis* formed only 0.4 per cent of the fleas on mole rats. In the plains, observations in the Cumbum Valley show that mole rats harbour *X. astia* almost to the exclusion of *X. cheopis*. Mole rats have been found quite susceptible to plague, and their rôle in the epidemiology of plague should therefore depend on the vector efficiency of the sort of fleas which parasitize them in the different areas.

Bandicoots (*B. malabarica*).—The bandicoot prevails largely in the immediate vicinity of habitations, either in or around house drains, rubbish heaps, cowsheds, etc. It is much bigger than the mole rat or any other South Indian plague rodent. Its head is narrow, contrasting with that of the mole rat. The tail is thick and blunt with well-marked annular rings and in length is only about a tenth shorter than that of the head and body together. Its coat is uniformly harsh with long spinous hair. In its wandering and scavenging habits, no other Indian plague rodent can compare with it except perhaps *Rattus norvegicus* of the seaport towns. Plague epizootics in certain areas are heralded by deaths among bandicoots, followed by rat and mouse falls. From its semi-domestic habitat it may be rightly said to form the intermediary in the extension of plague from house rats to wild rodents. It is also as susceptible to plague as *R. rattus*. In proportion to its size, it harbours large numbers of fleas. At Coonoor, it was found infested with *X. astia*, *X. cheopis*, *X. brasiliensis* and *Ceratophyllus* fleas, the specific flea indices decreasing in the same order. Its *cheopis* index was 1.2 during this enquiry.

Bush rats (*Golunda* species).—More than one species of *Golunda* are said to prevail in the Nilgiris, but all the specimens we got, except one not yet identified, were *Golunda ellioti*. In this hill station, the bush rat is found to harbour very few fleas. When present, these are either *Ceratophyllus* or *Stivalius*. On the other hand, in the Cumbum Valley these rodents are found to harbour only *X. astia* and no *X. cheopis*. The bush rat is easily identified by its flat ears, longitudinally grooved incisor teeth and the characteristic yellowish brown coat. It is a poor burrower, the nest, generally composed of coarse grass, leaves and small twigs, being usually found in shallow pits or in discarded burrows of other rodents. Its favourite habitat is under cover of thick hedge growths on the edges of cultivated fields where its characteristic runs can easily be recognized. As it usually confines itself to its own trodden path, it is easily led into traps laid along the runs. Though it is susceptible to plague, it may be said to possess only a negligible rôle as a reservoir of plague as it harbours few fleas and seldom *X. cheopis*.

Field mice (*Leggada booduga* Gray).—The field mouse prevails largely in cultivated fields and lawns. It is easily recognized from the house mouse by its smaller size and yellowish brown dorsal and white ventral coat. Although it is quite susceptible to plague, its rôle in the spread of plague is negligible since it carries very few fleas.

Flea counts.—The following table (I) gives the percentages of various fleas found on *R. rattus*, *B. malabarica* and *Gunomys kok* during the present enquiry as compared with those from a survey carried out by one of us (P. V. G.) in 1929.

TABLE I

Place	Rodents	Number of		Percentage of different flea species					
		Rodents	Fleas	X.a.	X.b.	X.c.	C.n.	Stiv.	L.m.
Coonoor (1939)	<i>R. rattus</i>	243	1,038	8.7	37.9	40.5	3.5	0.2	1.2
	<i>B. malabarica</i>	12	81	74.1	7.4	14.8	2.5

	<i>Gunomys kok</i>	8	24	..	8.3	8.3	83.3

X.a. = *Xenopsylla astia*.
X.b. = " *brasiliensis*.
X.c. = " *cheopis*.

C.n. = *Ceratophyllus nilgiriensis*.
Stiv. = *Stivalius* sp.
L.m. = *Leptopsylla musculi*.

The above table clearly shows that the predominating flea on *Gonomys* in Coonoor is *Stivalius* and in Ootacamund, *Ceratophyllus*. The flea which predominates on the bandicoot is *X. astia*, though *X. cheopis* also are largely present. On *R. rattus*, which is primarily concerned with epidemic plague, the flea which predominates in both towns is *X. cheopis* and next in order *Ceratophyllus* in Ootacamund and *X. brasiliensis* in Coonoor. Expressed more scientifically, the cheopis index of *R. rattus* (average number of cheopis per rat) for Coonoor (1939) was 1.73 and for Ootacamund (1929) it was 1.75. This evidence of parasitology may alone explain the endemicity of plague in the Nilgiris district. Thus, Hirst (1927) states that a cheopis index of one associated with moderate density of rat population would indicate potential danger of plague epizootics.

Examination of rodents and fleas.—All rodents obtained were carefully autopsied and those with suspicious signs were studied by cultural methods, animal inoculation, smear examination, etc. Three carcasses of *R. rattus* examined from Iduhatty village proved positive to plague. One hundred and twenty live fleas were collected from these specimens and plague infection proved in them. About half the number of these infected fleas were examined alive in capillary tubes. One of those (*X. brasiliensis*) which suggested infection from the blocked condition of its proventriculus was fed on a white mouse. The mouse contracted infection from this bite and succumbed on the 8th day with signs of acute plague, later confirmed by animal passage. No definite positive signs of plague were noted in any of the other rodents or fleas examined. It may be noted that they were mostly collected from areas where there has been no recent infection.

(2) *Plague transmission experiment with Stivalius and Ceratophyllus fleas.*—*Stivalius* fleas are plentiful in the Nilgiris, especially in and around Coonoor. They appear to become fewer as the altitude increases beyond Coonoor. Three sub-species of this flea, *Stivalius ahale*, *Stivalius aporus* and *Stivalius ferinus*, have been described by Jordan and Rothschild from the Nilgiris. The similarity between these sub-species is rather close, and while the sorting of killed, cleared, and mounted specimens is not difficult, the sorting of live ones requires considerable experience. Ordinarily for biological transmission experiments one should work with each sub-species separately. In the present work, however, for want of sufficient time in rearing individual species of fleas in artificial nurseries, *Stivalius* fleas collected off *Gonomys kok*, presumably a natural mixture of all the prevailing sub-species, were employed for the transmission experiments. While the results obtained may be deemed to fall short of strict biological accuracy regarding each of the sub-species, they must be true with respect to one or other of all of them, and therefore should satisfy all the requirements for practical application.

Five transmission experiments were carried out—*vide* table II for details. Special transmission cages of the type employed by the Plague Research Commission in India, obtained on loan from the Haffkine Institute, Bombay, were employed. White mice were used as the animal hosts, as these are said to have a uniform susceptibility to plague, and are, further, easy to handle. Every technical precaution was adopted to eliminate the chances of extraneous rats or fleas having access to the transmission cages, or the escape therefrom of infected animals or fleas. For each experiment a white mouse was artificially inoculated by the cutaneous

† Test mouse died of other causes.

route with a 48-hour broth culture of a recently isolated local strain of plague bacillus. Fleas purposely starved for a few days were introduced when the mouse showed signs of septicæmia preceding its fatal termination. To test the infectivity of these fed fleas, healthy mice were introduced after definite intervals. These test mice and the surviving fleas were tested for evidence of infection, either at the time of death of the mice or when the mice were killed about the time when the enquiry had to be wound up.

In the first experiment, where the fed fleas were put on the test mouse the same day, the latter died of acute plague on the third day. In the second and the third experiments, where the fed fleas were starved for 3 days, before being put on the test mice, the latter when killed showed certain post-mortem signs suggestive of plague and smears from their viscera showed plague bacilli. Pooled emulsion of the surviving fleas in the first experiment was injected into a guinea-pig which on being killed on the 14th day showed certain lesions of resolving plague. Crushed smears of fleas which survived the second and third experiments showed plague bacilli.

Employing similar technique, two experiments were carried out with *Ceratophyllus nilgiriensis*. One experiment had to be discounted as the test mouse died prematurely owing to other causes. In the second experiment, where fed fleas starved for 3 days were put on a test mouse the latter on being killed showed no evident post-mortem signs of plague. Two out of the 3 surviving fleas however showed numerous plague bacilli in their stomachs a week after they were fed on the infective mouse. Cultures from their stomach contents were also positive to plague.

It is clear from these experiments that *Stivalius* fleas can transmit plague at least up to 3 days after feeding on an infected host. If time had permitted the maximum period for which these fleas are capable of retaining infectivity could have been worked out and would have helped comparison. The flea which is infective for the longest period is really the most efficient vector, but such longevity experiments have been carried out only for very few of the known fleas. *X. cheopis* has been shown to remain infective for about a month under semi-natural conditions (George and Webster, *loc. cit.*).

It may also be reasonably concluded that *Ceratophyllus nilgiriensis* is at least a weak vector of plague among rodents inasmuch as they retained live plague bacilli in their stomachs for over a week. Another important point to be considered, in deciding the vector efficiency of these fleas, is whether they readily bite man. As there was plague in the district at the time, we did not experiment with the fleas collected from rats to ascertain this fact. Certain species of *Ceratophyllus* are already known to bite man readily, but we have not come across any authentic record about *Stivalius*. Local

enquiry has not helped us in getting any information on this point, but if these fleas, which are unusually big in size, were really vicious human biters, like *Pulex irritans*, such information would have been readily forthcoming.

It is perhaps appropriate here to mention that another flea which prevails here and which is absent on rats in the plains is *Leptopsylla musculi*. No transmission experiments were done with this flea during this enquiry, but it is already known from Chinese workers that it is a weak vector of plague and that it only reluctantly bites man. The other fleas, *X. astia*, *X. brasiliensis*, *X. cheopis*, *Pulex irritans* and *Ctenocephalus*, most of which have been found to infest the field rodents as well as the domestic rodents of the Nilgiris, require to be discussed in this connection. The first three *Xenopsylla* fleas are all known to be good vectors of plague, the last (*cheopis*) being, of course, the most efficient of all known fleas. *Pulex irritans*, or the human flea, is largely prevalent all over the district to the extent of being a regular scourge. These fleas have been supposed by various workers to be capable of spreading plague, though convincing experimental proof is lacking. The need for their control is therefore to be emphasized, especially during plague epidemics. *Ctenocephalus* fleas are not good vectors of plague among the rodents, as they feed only very reluctantly on hosts other than their specific hosts, dogs, cats, cattle, etc.

Discussion.—As pointed out in the earlier part of this report, the usual seasonal variations in the incidence of plague are not evident in the Nilgiris district. The explanation may perhaps be found in a review of the ecology and vector efficiency of the indigenous plague fleas of the district. *X. cheopis*—the tropical plague flea—transmits plague best between 68° and 78°F., and when the saturation deficiency is below 0.3 inch of Hg. It is also known that certain fleas, such as *Ceratophyllus fasciatus*, of temperate climates transmit plague best at temperatures about 10 to 15° lower than the optimum for *X. cheopis*. Therefore, in areas where the biological factors concerned in the spread of plague, both of warm and cold climates, co-exist, it is possible that the infection may be carried over in relays from season to season. Thus the observation of Colonel Russell, *i.e.*, that seasonal variations in the incidence of plague in the Nilgiris is not very evident, may be explained as due to the co-existence and interplay of more than one efficient plague flea.

As examination of wild rodents and their fleas on an adequate scale could not be carried out during the limited period of this enquiry, no definite proof could be adduced either for or against the existence of sylvatic plague in the district. The examination of the small number of specimens collected did not yield any positive results. We are in agreement with K. F. Meyer (1939) that only animal inoculation tests with pooled emulsions of wild rodent fleas on an

extensive scale could clinch the accuracy of the diagnosis of sylvatic plague. The crucial evidence of infection in wild rodents is difficult to obtain as their casualties occur either in their subterranean nests, or, if in the open, they fall a prey to carnivorous animals and birds. The report of Jellison (1939) on predatory and scavenger birds and their nests, offers the possible reason why it should be difficult for workers to detect plague infection in wild rodents during sylvatic plague surveys.

In the Nilgiris, the peculiar configuration of the land, the prevailing climatic conditions, the abundance of a variety of wild rodents and fleas (all complementary hosts and vectors of plague), the common occurrence of human and rodent plague sporadically in areas apparently independent of traffic and the occurrence of pneumonic plague more frequently than in the plains, are features which are in line with those in countries where sylvatic plague has actually been proved to exist. It is, therefore, suggested that sylvatic plague either actually exists now, or the factors are such as may contribute towards its onset at any time.

Summary

1. A review of the incidence of human plague in the Nilgiris district from 1903 to 1939 is given. Factors relating to sylvatic plague are also discussed.

2. A limited rodent and flea survey of the district with reference to plague has been carried out. One thousand and nineteen rodents and 1,939 fleas collected, formed the basis of this survey. All the specimens of rodents and fleas except those utilized for special experiments were examined for evidence of plague infection and the results are recorded. Plague infection was noted only in 3 rodents and 120 fleas, but these were collected from an infected area.

3. Transmission experiments with *Stivalius* and *Ceratophyllus* sp. were carried out and their vector-efficiency is discussed. *Stivalius* fleas transmitted plague to a white mouse 3 days after separation from an infected host. *Ceratophyllus nilgiriensis* were found to harbour plague bacilli in their alimentary tract up to 7 days after having fed on an infected host.

Acknowledgment.—Our thanks are due to Lieut.-Colonel C. M. Ganapathy, M.C., I.M.S., and Dr. C. G. Pandit, for valuable advice during the enquiry, to Major H. W. Mulligan, I.M.S., for laboratory facilities provided, to Lieut.-Colonel S. S. Sokhey, I.M.S., for the identification of the sub-species of *Stivalius* fleas and for help in the transmission experiments, to Mr. A. J. Acaster, Secretary, United Planters' Association of South India, for help rendered in the collection of material from various estates and to Lieut.-Colonel H. E. Shortt, I.M.S., for valuable suggestions and criticism in the preparation of this paper.

ON A PLASMODIUM SP. OF THE MALAY CHESTNUT-BELLIED MUNIA [*MUNIA ATRICAPILLA ATRICAPILLA* (VIEILL.)]

By B. M. DAS GUPTA

and

L. B. SIDDONS

From the Department of Protozoology, School of Tropical Medicine, Calcutta
(*Malaria Transmission Inquiry* financed by the Indian Research Fund Association)

Introduction.—During the examination of blood films from over 300 birds comprising fowls, a duck, a pigeon and a variety of sparrows and munias, parasitic infections due to a plasmodium were observed in three out of sixty-one specimens of the Malay chestnut-bellied munia [*Munia atricapilla atricapilla* (Vieill.)] examined. The infected birds had been imported and were obtained from dealers. Scott (1927) recorded a parasite of the order *Hemosporidia* in the same host from a bird which had died in the Zoological Society's Gardens in London, but the infection was too scanty to enable him (and Wenyon) to determine whether it was *Plasmodium praecox* or a haemoproteus.

Method of study.—In the present series of observations the strain was maintained by blood inoculation in the natural host and in the white-throated munia [*Uroloncha malabarica* (Linn.)] when the former was not available in the market. Both are small birds and 1/20 c.cm. of citrated blood was considered a suitable quantity for inoculation, either into the wing vein or intramuscularly into the leg.

Combined Leishman-Giemsa stain was used: prolonged staining was necessary to bring out the characteristic sex differences of the gametocytes.

Morphology (stained parasites).—The youngest form is a tiny rounded body consisting chiefly of chromatinic substance (figure 1). Soon a vacuole forms, the cytoplasmic content increases, and the parasite assumes the shape of a stout ring (figure 2). The ring stage, however, appears to be very transient, in that it is scarcely found even in blood showing heavy infections. As growth proceeds, pigment appears in the form of brown-black granules, and the cytoplasm looks spongy (figures 3 and 4). The growing parasite displaces the nucleus of the host cell to one side or more commonly

to one pole, or even out of the cell (figures 5, 12 and 14). At the early stage of schizogony the chromatin becomes diffuse and granular (figure 6). Segmentation of the chromatin now takes place. There is an aggregation of pigment granules even at an early stage of schizogony (figure 7) and when the schizonts are fully developed the pigment collects as a single mass usually in the centre of the parasite (figure 8). The mature schizonts are round; the number of merozoites varies from 8 to 22. Schizonts showing 12 merozoites form the majority; those with 22 merozoites are exceedingly rare. Gametocytes are slightly oval or rounded bodies. They have irregularly distributed pigment. In some, the pigment granules are coarse and discrete (figure 13), while in others they are fine and coalesce together to form irregular masses (figure 14). The male gametocyte takes on a faint pinkish tinge; the nucleus is diffuse and stains badly (figure 15). The cytoplasm of the female stains a deep blue colour. The nucleus is more compact and stains more deeply than in the male (figures 13 and 14). In well-stained preparations a small spherical deeply staining body can be made out; this is probably a karyosomal structure.

The gametocytes appear very early in the peripheral blood, even at the earliest stage of the infection. They are always present in the blood even when other phases of the parasite are absent, or present in very scanty numbers.

Multiple infection of corpuscles is not uncommon. As many as four parasites have been found to occur in one corpuscle (figures 5 and 12) in heavy infections. Parasites were very scanty in the birds (*Munia atricapilla*) which showed the natural infection, but often by a series of sub-inoculations into other birds of the same species and into another species of munia (*Uroloncha malabarica*), heavy infection could be produced. In smears taken from a heavily infected bird almost every stage of growth of the parasite has been found. In experimentally infected birds the incubation period is about 10 days. For a week or so the parasite increases in number and thereafter the infection begins to decline. Very scanty infection persists for a long time and eventually it probably dies out altogether. As a rule pathogenicity is slight, and in only two instances of exceptionally heavy infection could the death of the bird be ascribed to harmful effect of the parasite.

Host relationship.—The host specificity was tested for nine species of birds (vide table).

The following conclusions are drawn from the results :—

- (1) Species of *Uroloncha* are extremely susceptible to the plasmodium of *M. atricapilla*, even more so than its natural host.
- (2) Canaries are slightly susceptible.
- (3) The plasmodium is not inoculable to the Indian house sparrow.
- (4) Java sparrows, the white-eye, and the domestic fowl, ducks and pigeons have been

TABLE
Showing host specificity of the parasite

* Only birds which survived ten days (the minimum incubation period of the parasite) or longer are included. Controls (*M. atricapilla* or *U. malabarica*) were provided for all species except the white-eye and the domestic duck.

tried as possible hosts, but the observations are too few to draw any conclusion from the negative results with these birds.

The infections produced in canaries were light and never showed an acute stage, nor was any pathogenic effect observed. In one of these birds examined twelve days after inoculation and found positive with a scanty infection, the parasites disappeared from the peripheral blood roughly at a time when a control munia (*U. malabarica*) showed a moderately heavy infection.

Invertebrate hosts.—Two batches of *Culex fatigans* and two of *Stegomyia fasciata* were fed on munias showing a large number of gametocytes, but neither oöcysts nor sporozoites developed in 22 *Culex* and 40 *Stegomyia* examined at intervals varying from eight to thirty days after the date of the single blood meal.

Systematics.—Giovannola (1934) and Manwell (1938) have classified the avian plasmodia on the bases of the following morphological characters :—

1. Form of the gametocytes
2. Alterations, if any, in the host cell
3. Number of merozoites
4. Character of the pigment of gametocytes
5. Form of the schizonts.

Manwell has also employed a biological criterion, namely, behaviour in the canary.

Morphologically, the plasmodium of the munia is exceedingly similar to *P. praecox*.

Gr. & F. : they agree in the form of the gametocytes and of the schizonts, and in both the nucleus of the host cell is frequently expelled. The pigment of the gametocytes of *præcox* is stated to be fine and dot-like (Giovannola, loc. cit.; Manwell, loc. cit.) and that of the plasmodium of the munia can only be described as varying from fine particles to coarser, discrete granules. Yet this character is not considered of separatory value since size, distribution, and other features of the pigment are known to be highly variable. Moreover, judging from films of *P. præcox* from Madras sparrows, no noteworthy pigmentary differences could be detected. Nor does the number of merozoites in mature schizonts indicate more than that the plasmodium of the munia may be a separate strain of *P. præcox*, for this species is known to consist of at least three strains differing in this character. The German strain produces 16 to 32 merozoites, the American 8 to 15, and Huff (1937) has described and named a third, *P. relictum* (*præcox*) var. *matutinum* from the American robin, which produces 10 to 22 merozoites, and has also striking biological differences from the other strains.

There are, therefore, no morphological characters which would serve to indicate that the plasmodium of the munia cannot be classified under *P. præcox*.

Biologically, however, there are some interesting differences, so far as the available evidence goes. The fact that Calcutta sparrows could not be infected from the munia is very significant. There is a possibility that the local sparrows have acquired immunity to *præcox*. On the other hand, Knowles (1935) reported that he was studying this species in sparrows in Calcutta, using a strain obtained from Kasauli*.

There are also differences affecting infections in the canary. *P. præcox* has a definite acute stage in this bird, in which the parasite level is high (Manwell, loc. cit.), and it is known to be highly pathogenic, though not so var. *matutinum*. The parasite of the munia, on the other hand, only produces infections of very light intensity in the canary which are by no means pathogenic. Whether the latter results are dependent on the quantity and parasite content of the inoculum requires further investigation.

Failure to infect *Culex fatigans* and *Stegomyia fasciata* may also be an expression of separate identity to other strains of *præcox*.

On the available evidence, therefore, it is possible that the plasmodium of the munia represents a separate strain or variety of *P. præcox* (which it is tentatively proposed to name *P. præcox* var. *muniae*). Further studies on its biology are undoubtedly necessary to define its exact position.

Other blood parasites observed during the investigation.—Infection with hæmoproteus and toxoplasma was observed in *U. malabarica* and the house sparrow respectively. A trypanosome was also found in *U. malabarica* and it is described in a separate communication.

Microfilariae all looking almost alike were present in numbers in the blood of *Munia atricapilla*. The adults were searched for in the tissues and one male specimen was found and identified as *Diplostriaria dubia* by Dr. N. Bhaduri.

Summary

A strain of *Plasmodium præcox* (*relictum*) Gr. & F. is described from the Malay chestnut-bellied munia [*Munia atricapilla atricapilla* (Vieill.)] which produces 8 to 22 merozoites and appears biologically different from other known strains of the species. It is provisionally named *Plasmodium præcox* var. *muniae*.

Acknowledgments

The authors desire to thank Dr. Baini Prasad, D.Sc., for identification of some of the birds used in this investigation, Lieut.-Colonel H. E. Shortt, C.I.E., and Major H. W. Mulligan for helpful suggestions. Their thanks are also due to the artist, Mr. H. M. Roy, for preparing the excellent coloured drawings.

PLATE IX

PLASMODIUM OF THE MALAY CHESTNUT-BELLIED MUNIA (DAS GUPTA AND SIDDONS)

TRYPANOSOME OF THE WHITE-THROATED MUNIA (DAS GUPTA AND SIDDONS)

ON A TRYPANOSOME OF THE WHITE-
throated MUNIA—*UROLONCHA
MALABARICA* (LINN.)

By B. M. DAS GUPTA
and

L. B. SIDDONS

From the Department of Protozoology, School of
Tropical Medicine, Calcutta
(Malaria Transmission Inquiry financed by the Indian
Research Fund Association)

In connection with our studies on bird malaria 41 specimens of this species of bird amongst others have been examined.

This bird is found practically all over India and in the dry maritime parts of Ceylon. It ascends the Himalayas up to about 6,000 feet, below Simla. To the east, it occurs in Eastern Bengal, but apparently not in Assam, or in the Bengal districts north and east of the Bay of Bengal. On the west, it is found in Baluchistan and Afghanistan, and up to the Arabian coast.

Only two specimens showed scanty infection with the trypanosome. Four birds of the same species were inoculated into the muscles of the leg with the infected blood. These inoculated birds were examined daily from the fourth day onwards. On the tenth day, extremely scanty trypanosomes were found in one of them. It was necessary to examine several smears before a single flagellate was detected. From this time it was noted that although the parasite count was never high it showed marked fluctuation. For example, on one occasion only one trypanosome was found after a very careful examination of three fresh coverslip preparations, but two days later about half a dozen flagellates were found in a single smear. The trypanosomes persisted in the blood of both naturally and experimentally infected birds for more than two months till the birds died. This parasite does not seem to produce any pathogenic effect on the host. The death of the infected birds was probably caused by repeated bleeding for preparing smears and for cultural purposes.

The infected blood was inoculated into N.N.N. medium and incubated for weeks at 18° to 20°C. No growth was obtained in any of the six tubes used.

Description of the flagellate.—When examined in the living state under a coverslip the trypanosome is seen to move with moderate rapidity. The undulating membrane is in constant motion and the free flagellum lashes about vigorously. A thin flagellum-like structure is found at the posterior end of the body, which exhibits slow lateral movements.

The dimensions of the trypanosome based on the measurement of forty individuals are as follows:—

TABLE I

Length of body without flagellum ..	36.75μ-52.25μ
Free flagellum ..	7.50μ-10.75μ
Breadth of body at the widest part ..	5.50μ- 8.75μ
Distance from kinetoplast to the centre of nucleus ..	7.75μ-10.75μ

Measurements of the flagellate were taken from blood smears, which were exposed to osmic acid vapour for 30 seconds and then immersed in a jar of absolute alcohol for 10 minutes. These smears were very thoroughly washed with distilled water and stained by Giemsa's stain for an hour. The following method as advocated by Knowles (1928) was employed for measurement of the trypanosome:—

With the 1/12th inch oil-immersion lens, a no. 8 ocular and a reflecting prism, the trypanosomes are projected on to a sheet of paper. Their outlines are drawn, the parabasals and the nuclei indicated. The stage micrometer is then projected on the same sheet of paper and drawn on it. With a scale the divisions corresponding to 10μ are divided into tenths, i.e., 1μ. A line is drawn through the middle of the length of each flagellate and the length of the body, the length of the free portion of the flagellum and the maximal width, etc., are measured with a divider set at 1μ or 2μ.

With regard to general morphology, this is a monomorphic trypanosome. The nucleus is situated about the middle of the body near the convex margin, sometimes occupying nearly the entire depth of the organism (*vide plate IX, e and f*). The kinetoplast also lies near the convex edge at some distance from the posterior end. The undulating membrane is well developed. The axoneme is extended well beyond the anterior extremity as a free flagellum. There are distinct striations on the surface of the body and they extend throughout the entire length. The most striking feature of this flagellate is that its posterior end is prolonged into a long thin caudal process which is of about the same length as the free flagellum; it is even longer in some cases.

It appears from the literature at our disposal that the only avian trypanosome which shows some resemblance to this is a trypanosome described by Hanna (1903) from the blood of the domestic pigeon in India, and named *T. hanna* by Pittaluga (Wenyon, 1926). For comparison, the measurement of different parts of the body and other important morphological characters of the trypanosome of the pigeon and that of the flagellate under discussion are given in table II:—

TABLE II

	TRYPANOSOMES	
	<i>Trypanosome of the white-throated munia</i>	<i>Trypanosoma hanna</i>

	TRYpanosomes	
	Trypanosome of the white- throated munia	<i>Trypanosoma hannai</i>
Length of the free flagellum.	7-11 μ	6-8 μ
Distance of the kinetoplast from the centre of the nucleus.	8-11 μ	4-6.5 μ
Other characters—		
<i>Trypanosome of munia.</i> —The posterior end is prolonged into a long thin caudal process which is of about the same length as the free flagellum or even longer. There are marked longitudinal striations on the surface of the body.		
<i>Trypanosoma hannai.</i> —Scattered through its substance, especially towards each end, are granules of a dark violet colour. The anterior end of the body is much elongated, pointed and gradually merges into the flagellum, so that it is difficult to say where the body ends and the free portion of the flagellum begins. At the posterior end the body also tapers and ends in a pointed extremity; in some forms distinct evidence of longitudinal striation is observable.		

As shown in table II the chief points which distinguish the trypanosome of the white-throated munia from that of the pigeon are the possession of a long caudal process by the former and marked disagreement in the distance of the kinetoplast from the posterior end of the body and from the centre of the nucleus. Besides, the trypanosome of the pigeon is conspicuous by the presence of deep staining granules scattered throughout the cytoplasm, especially at the ends. The trypanosome of the white-throated munia seems, therefore, to represent a new species and the name *Trypanosoma knowlesi* is proposed in honour of the late Lieut.-Colonel R. Knowles, I.M.S.

Summary

A new species of trypanosome (*Trypanosoma knowlesi*) is described from the blood of a white-throated munia (*Uroloncha malabarica*).

Acknowledgment

Our grateful thanks are due to Dr. Baini Prasad, D.Sc., for specific identification of the munia referred to in this paper.

DIPHTHERIA : DIFFICULTIES IN THE MORPHOLOGICAL DIAGNOSIS OF *CORYNEBACTERIUM DIPHTHERIAE*

By C. L. PASRICHA

MAJOR, I.M.S.

Professor of Bacteriology and Pathology

and

K. BANERJEE

Assistant Professor of Pathology

(From the Department of Bacteriology and Pathology, School of Tropical Medicine, Calcutta)

ALTHOUGH it is well known that at times it is extremely difficult to decide whether an organism seen in a film belongs to the genus *Corynebacterium*, this fact is often forgotten particularly by those laboratory workers who are but rarely called upon to examine a culture for *Corynebacterium diphtheriae*. The following experiment illustrates this well.

A throat swab was taken from a child suffering from sore throat and fever. The swab had been taken more for the purpose of excluding diphtheria than on any clinical indications.

A cultural examination was made and the next morning a report was sent to the effect that *C. diphtheriae* had been isolated. The child who had no complaints and appeared perfectly well when the report was received was given 16,000 units of diphtheria antitoxin. At the same time swabs were taken from the child again and from the immediate contacts in the household—a total of eight swabs. Inoculations were made on Loeffler's medium and also a subculture of the growth on Loeffler's medium inoculated with the first swab from the patient. Smears were made next morning from the growth on the eight tubes of Loeffler's medium. These were stained with Ponder's stain and these eight preparations were submitted in turn to seven bacteriologists all of whom had had more than ten years' experience in diagnostic laboratories.

Two of the seven workers reported that they found no organisms suggestive of *C. diphtheriae* in any of the eight smears. It may be noted that these two workers had had more experience in handling suspected diphtheria material than any of the others. The other five reports are summarized below.

Subsequently careful and exhaustive examinations were made of the eight cultures and in none of them was *C. diphtheriae* isolated. Virulence tests (both the intracutaneous and subcutaneous tests) were made with the original culture which had been reported as positive and with cultures from subsequent swabs from the patient. All these tests gave negative results.

These results are recorded to stress the difficulties in the laboratory diagnosis of diphtheria and to indicate the advisability of a central diphtheria laboratory to which all doubtful

THE STERILITY AND POTENCY OF INJECTABLE SUBSTANCES

(i) GLUCOSE SOLUTIONS

By C. L. PASRICHA
MAJOR, I.M.S.Professor of Bacteriology and Pathology
and

K. S. MALIK

(From the Department of Bacteriology and Pathology,
School of Tropical Medicine, Calcutta)

FOURTEEN samples of commercial preparations of glucose for intravenous use were examined for sterility and strength of glucose present. Original packages of each product were bought in the open market. Standard methods of examination were used and these need not be detailed here.

Except for one ampoule which had an obvious growth of fungi and which was not further examined, all the 72 ampoules tested were sterile (test cultures incubated both aerobically and anaerobically). The results summarized below are the average of the examination of three ampoules of each product. There was no appreciable difference in the results obtained with different ampoules, provided the ampoules were of the same batch number. In two products ampoules with different batch numbers were included in the same outer packing.

(Continued from previous page)

specimens can be submitted for confirmation of diagnosis. These results also stress the importance of evaluating technical procedures and that the evaluation depends on the amount of experience a laboratory worker has had with certain given methods.

Results of the morphological examination by seven bacteriologists of films from Loeffler culture of swabs from a case of sore throat and from six contacts of this case

Swabs from	BACTERIOLOGISTS

+ = when the report stated that *C. diphtheriae* were seen.+(?) = when there was no definite conclusion made but the report stated that 'bacilli with metachromatic granules or bars seen arranged in a manner suggestive of *C. diphtheriae*'.

In order to avoid any personal bias the contents of three ampoules of each preparation were placed in separate tubes and the tubes given serial numbers and so arranged that it was not possible to identify the products of any company whilst the estimations were being made. The analysis was made after all the tests were completed.

Results of the examination of fourteen samples of commercial glucose solutions for intravenous use

Number	pH of the solution	Percentage of glucose claimed	Percentage of glucose found	Percentage of glucose found to the amount claimed
1	3.8	25.0	15.4	61.6
2	5.3	25.0	22.5	90.0
3	3.9	25.0	22.9	91.6
4	5.1	25.0	23.8	95.2
5	4.4	25.0	24.9	99.6
6	4.4	25.0	24.9	99.6
7	4.3	25.0	24.9	99.6
8	4.9	25.0	25.1	100.4
9	4.1	25.0	25.2	100.8
10	5.0	25.0	25.3	101.2
11	4.2	25.0	25.3	101.2
12	4.4	25.0	26.2	104.8
13	4.5	12.5	13.1	104.8
14	4.9	50.0	49.8	99.6

From the tabulated results it will be seen that :—

(1) One product (no. 1 in the table) is unsatisfactory. Whereas it was claimed to contain 25 per cent glucose it was found to have 15.4 per cent or only 61.6 per cent of the glucose that the ampoules were labelled to contain. Further ampoules of this particular sample were examined with similar results.

(2) Three products (nos. 2, 3 and 4 in the table) also contained less glucose than the amount claimed. These three samples contained 90.0, 91.6 and 95.2 per cent of the amount that they should have contained. Control experiments with glucose solutions of known strength showed that the experimental error in the estimations was less than ± 1 per cent.

(3) The remaining ten products were satisfactory. These were all preparations of commercial firms of established reputation and the results show that two of the samples contain a little more glucose than the ampoules were labelled to contain.

An attempt was made to correlate the reaction of the solution with the quality of the glass ampoules used by the different manufacturers. The ampoules after thorough washing were tested according to the standards laid down in the British Pharmacopoeia. The majority of the manufacturers used good quality neutral glass, in two products the glass ampoules were of inferior quality alkaline glass and in one box there were four ampoules of

THE USE OF BACTERIOPHAGE FOR FREEING PROTOZOAL CULTURES OF CONTAMINATING BACTERIA

(ISOLATION OF *Leptospira icterohæmorrhagiae* FROM A MIXED INFECTION IN GUINEA-PIGS)

By A. J. H. DEMONTE, D.P.BACT., I.M.D.

and

S. K. GUPTA, M.B., B.T.M.

(From the School of Tropical Medicine, Calcutta)

CULTURES of leptospira are liable to contamination with bacteria when passaged through guinea-pigs and are often lost when the contaminants are organisms pathogenic to those animals.

Recently, our advice and help was sought for the purification of a strain of *Leptospira icterohæmorrhagiae* which was isolated from the urine of a patient by injecting a young guinea-pig, but which had become contaminated during subsequent passage through another such animal. Among other measures, it was decided to adopt the following two procedures to obtain a pure culture of the leptospira :—

(a) By filtration through L₂, Pasteur-Chamberland filtering candles.

(b) By treating the material containing the two organisms with bacteriophage active against the bacterial contaminant.

We undertook to carry out the latter procedure.

The contaminating bacteria were isolated by plating on agar and identified as belonging to the salmonella group. They fermented glucose, mannite, maltose, arabinose and dulcitol with the production of acid and gas; lactose, saccharose, and salicin were not affected. Litmus milk became strongly alkaline; the methyl red test was positive and Voges-Proskauer reaction negative; indole was not produced and the

(Continued from previous page)

neutral glass and two ampoules of obviously inferior quality alkaline glass. It was not possible to correlate the reaction of the solution with the quality of the glass.

Summary

The results of the examination of fourteen samples of glucose solutions for intravenous use are recorded. One of the products contained 15.4 per cent glucose, whereas it was claimed to contain 25 per cent glucose. This sample contained only 61.6 per cent of the glucose that the ampoule was labelled to contain. Three other products contained 90.0, 91.6 and 95.2 per cent of glucose claimed. The rest of the samples were satisfactory.

These results stress the necessity of careful supervision during manufacture and the need of some central control of glucose solutions—one of the commonly used therapeutic products.

organisms were actively motile. They were agglutinated by *Bact. paratyphoid B* serum (H & O) to full titre. Pure H serum in the specific phase was not available for determining exactly, the identity of the organisms and the strain was provisionally labelled as *Salmonella typhi murium* (*Bact. aertrycke*). On exposure to the action of bacteriophage, the strain was found susceptible to the action of stock bacteriophage which acted on *S. typhi murium* strains. Preliminary study showed that, by subjecting the salmonella strain to the action of this bacteriophage, lysis was complete in four hours and that this lysis was maintained for more than three days. A potent phage, therefore, capable of lysing the contaminating bacterial strain, was now available.

Liver and kidney tissue containing the two organisms was divided into two portions of 2 c.c.m. each. To one, 2 c.c.m. of the above bacteriophage were added; to the other a like amount of papain-digest broth (which was the medium used for the propagation of the phage) was added. Both portions were kept at room temperature in the dark for five hours, after which 2 c.c.m. of each portion were injected, separately, into young guinea-pigs intraperitoneally. The guinea-pig infected with the phage-treated portion died on the fourth day, exhibiting the typical post-mortem appearance of *Leptospira icterohæmorrhagiae* infection. Microscopic examination showed leptospira to be present and *S. typhi murium* were also isolated from the peritoneal fluid and heart's blood of the animal. The control guinea-pig (inoculated with the portion not treated with phage) died on the fifth day exhibiting the same jaundiced appearance. Leptospira and *S. typhi murium* were found by examination to be also present. This attempt, therefore, was not successful.

A second attempt was made, but this time the material containing the co-existing strains was first centrifuged to throw down the gross particles of liver and kidney tissue and sand. (Sterile sand was used to help in grinding up the tissues.) The supernatant fluid was divided into two portions and treated as previously, kept at room temperature in the dark for five hours, and inoculated separately into two guinea-pigs.

The animal injected with the phage-treated portion died during the night of the eighth day. There was intense jaundice, petechial haemorrhages, and *Leptospira icterohæmorrhagiae* were seen by microscopic examination of the peritoneal fluid. They were also present in the liver and kidneys of this animal. No bacteria were seen and broth and agar media inoculated with peritoneal fluid, heart's blood, ground-up liver and kidney material of the animal remained sterile. The control animal died on the seventh day also exhibiting typical signs of *Leptospira icterohæmorrhagiae* infection. Leptospira and the co-existing *S. typhi murium* were found to be

MARCH, 1941]

NOTES ON COMMON SKIN DISEASES : GHOSH

present by dark-ground examination and by culture.

Ground-up tissue from the liver and kidneys of the guinea-pig injected with the phage-treated portion was inoculated into a second animal which was killed on the fifth day. Symptoms of intense jaundice had developed and actively motile leptospiræ were again present in the peritoneal fluid in large numbers and again we failed to isolate the *S. typhi murium* strain. Vervoort's medium for the growth of leptospiræ was not available then, so a third guinea-pig had to be inoculated to keep the strain going. This animal was definitely ill on the third day, jaundice being marked. Peritoneal fluid was removed and examination showed that *Leptospira icterohæmorrhagiae* were present in large numbers. The animal was killed and blood from the heart was inoculated into agar, broth and Vervoort's medium. The liver and kidneys of this animal were ground up and also inoculated similarly. A good growth of *Leptospira icterohæmorrhagiae* was obtained in Vervoort's medium while the agar and broth inoculations produced no growth and the medium remained sterile.

Three more experiments were put up; one was a repetition of the first experiment (where the phage was allowed to act on the bacterial strain in the presence of gross organic matter); another was a repeat of the second experiment (in which the gross liver and kidney tissue was removed by centrifugation) and the last was one in which the gross matter was removed by filtration through kieselguhr-impregnated filter paper. Controls as already described were put up for the first two while that for the third was one in which papain-digest broth was added to the liver and kidney material that had been filtered. In the first experiment of this series both the test and control guinea-pigs developed jaundice and on their death showed the presence of both leptospiræ and *S. typhi murium*. In the second and third experiments of the series leptospiræ only were present and were grown in pure culture in Vervoort's medium. Both the control pigs showed the presence of the two co-existing strains.

Summary

A strain of leptospiræ had become contaminated with a salmonella group of organisms during passage through a guinea-pig.

The separation of the mixed infection and the growth of *Leptospira icterohæmorrhagiae* was effected by exposing the mixture to the action of a potent bacteriophage active against *S. typhi murium* and subsequent inoculation into guinea-pigs.

This action could not be obtained when gross organic tissue, like that obtained by grinding up infected liver and kidney tissue, was present. Removal of the gross matter by filtration

NOTES ON COMMON SKIN DISEASES

I. RINGWORM OF THE FOOT

By L. M. GHOSH, M.B. (Cal.), D.T.M. (L'pool)
(From the School of Tropical Medicine, Calcutta)

Synonyms.—Bengal (Hong Kong, Singapore, etc.) rot, mango-toe, athlete's foot and foot tethers are synonyms for ringworm of the foot.

The disease is caused by a fungus, chiefly the *Epidermophyton floccosum*, and the nidus of infection is usually the feet, between the toes, especially the fourth and fifth toe, and the groin area. From the toes the infection spreads to the other parts of the foot and also to the body. Sometimes the primary site may be the dorsum of the great toe.

For those who are in the habit of wearing socks and shoes for long hours, once the part is affected, it is difficult to get rid of the infection altogether, as heat, moisture and friction favour the growth of the infective organism.

In the first stage the epidermis of the skin becomes whitish, sodden, and peels off easily, then small pits, where the horny layer seems to have been eaten away, appear. If left untreated these may lead to cracks, fissures, and ulcerations. Secondary pyogenic infection at this stage is very common and inflammation of the areolar tissue (cellulitis) is not an uncommon incident.

With the advent of the cold weather, the condition apparently gets better, only to recur in the next hot weather and monsoon months.

The disease may confine itself to the toes, but quite often it extends to the instep and the sole of the feet, and may even spread to the other parts of the body.

After some time, a couple of years or so, the continuous irritation together with the toxins produced by the fungus may give rise to a condition of hypersensitivity of the skin with the resultant allergic symptoms of various kinds.

A common manifestation is the formation of irritating blisters under the skin of the sole of the feet and palms of the hands, a very distressing condition indeed. Erythematous and papular rashes on the flexors of the elbows and knees, and erythematous scaly eruptions on the body are also seen.

Prophylaxis.—1. In the tropics, it is advisable to wear white cotton socks which can be boiled daily.

2. During the bath in the morning and evening, wash the feet well with hot water or

(Continued at foot of next page)

(Continued from previous column)

through kieselguhr paper or by centrifugation was necessary.

We are grateful to Dr. B. M. Das Gupta who supplied us with the infected liver and kidney tissues.

VITAMIN A AND CAROTENE RESERVES IN HUMAN LIVERS

By B. AHMAD

and

P. K. SESHAN*

(From the Department of Biochemistry and Nutrition,
All-India Institute of Hygiene and Public Health,
Calcutta)

It is well known that liver is the store-house of vitamin A in the body. Under conditions of vitamin-A sub-nutrition, these reserves are depleted, while, when the food has been rich in vitamin A, a considerable amount of the vitamin is deposited in this organ. Experiments on animals indicate that the liver is capable of storing exceedingly large amounts, even as large as the requirements of an entire life span. The quantity of vitamin A present in the liver may serve as an index of the level of nutrition of an individual with respect to this factor. Though this will be only true under normal conditions of health, as it has been observed that in certain diseases spontaneous excretion of vitamin A may occur leading to depletion of the liver reserves.

* A worker under the Endowment Fund of the Calcutta School of Tropical Medicine.

(Continued from previous page)

preferably with warm lysol lotion 10 drops to one pint; then wipe them dry with the ordinary methylated spirit and dust them with powder; any ordinary talcum powder will do.

Treatment.—Before the ulcerative stage has set in, wash the feet twice daily as above, and then apply one of the following:—

(a)

B			
Acidi salicylici	gr. xx	
Acidi acetici dil.	m. xxx	
Spiritus rectificatum ad	5i	

Or (b)

Resorecinol	5i	
Tineturam benzoini com- positum ad	5i	

If the feet are painful and inflamed, apply a hot fomentation with aeriflavin (1—5,000), or boric lotion (1—20) during the day, followed by application of a mild antiseptic ointment at night, such as boric ointment, or dilute ammoniated mercury ointment, until the inflammatory condition subsides. At this stage water should be avoided altogether. When the inflammation subsides entirely, 4 per cent gentian-violet lotion made up with 10 per cent alcohol should be applied twice daily, after washing and drying the feet, until the ulcerative lesions are completely healed up. When the ulcers are healed and the parts look healthy, then the salicylic acid with spirit may be applied at night and dusting powder during the day after the bath.

Moore (1937) has studied the vitamin A and carotene content of human livers in health and disease. He observed comparatively high reserve of the vitamin in diabetes and thyroid diseases, and moderate reserves in persons dying as a result of poisoning. While in quite a large number of common diseases low vitamin-A reserves were observed, e.g., pneumonia, septicaemia, heart disease, and nephritis. In liver affections, such as cirrhosis, often no vitamin A was observed in the liver.

Under normal conditions of health the determination of vitamin-A reserves in the liver can constitute an important method of assessing dietary history as well as the state of vitamin-A nutrition of an individual. At the same time it can give us information of the conditions apart from those of deficiency under which vitamin-A reserves might be low. Such information will be useful in practical nutrition as it would indicate higher vitamin-A requirements under the conditions.

No studies on the vitamin-A content of human livers have been reported in India. It is interesting to know the average liver reserves of Indians in health, at different social and economic levels and at the same time, the effects of tropical diseases on the stores present in the liver. With this object in view we started a survey in Calcutta of vitamin-A reserve in human livers obtained from the autopsies of the Calcutta police morgue. In this paper some preliminary observations are recorded.

The vitamin A and carotene content of the livers were examined by the well-known absorption spectrophotographic methods. Vitamin A and carotene enter completely the non-saponifiable portion of the fats contained in the liver and have specific absorption bands, viz., 3280 Å for vitamin A, and 4600 Å for carotene. The livers were obtained immediately after the autopsy. Suitable quantities of it were minced and dissolved by warming up in a small quantity of 10 per cent alcoholic potash. The viscous solution so obtained was repeatedly extracted in cold with ether. The ethereal extract was carefully washed with water and the solvent evaporated off in a current of nitrogen. The solid residue constituting the non-saponifiable portion of the fat was dissolved in a suitable quantity of cyclohexane for spectrographic study. The absorption coefficient of this solution at 3280 Å was measured by photographing the absorption spectrum using a quartz spectrograph fitted with a photometric equipment consisting of Hufner prism, Schiebe cells, rotating sector and a Tungsten steel spark (Zeiss). The coefficient for 1 per cent solution in a 1 em. column of liquid multiplied by a conversion factor of 53.33 give the vitamin-A contents in micrograms ($\mu\text{g.}$) per gramme. For the determination of carotene, the absorption coefficient was measured using a visual spectrum step-photometer fitted with a filter transmitting 4600 Å (Pulfrich Zeiss). The absorption co-

efficient of a 1 per cent solution in a 1 cm. column multiplied by a conversion factor of 1200 gives the carotene content in μg . carotene per gramme.

The following table gives the results of vitamin A and carotene content of 16 samples studied so far. They contain 9 cases of accidents, 3 cases of heart failure, 3 cases of opium poisoning and 1 case of snake bite. Values are tabulated as the content per gramme of fresh liver, as well as the total content of the whole liver. The economic level of the person is

Though the data available is quite inadequate to permit any general conclusions, it is obvious that liver reserves of vitamin A were exceedingly low in these persons when compared to the data obtained in other countries through similar studies. These data are presented to indicate the scope of such studies and the trend of values of vitamin reserves in Indians in health and disease.

The authors desire to thank Major D. Ahmad, Calcutta Police Surgeon, for supplying samples of liver.

given as to indicate the type of diet they were likely to have taken.

From this table it will be seen that the vitamin-A values range from 3 to 58 μg . per gramme, and carotene values from 0.3 to 7.9 μg . per gramme of wet liver. For the working-class people as shown by this small sample, the average concentration of vitamin A in the liver is between 7 to 10 μg . per gramme. For the middle class people, the concentration is higher—probably in the neighbourhood of 23 to 27 μg . per gramme.

Curiously enough a high concentration was obtained in 3 cases of opium poisoning (over 14 μg . per gramme). In the one case of snake bite the liver contained exceedingly low amounts of vitamin A.

Summary

The vitamin A and carotene content of the livers of 16 persons obtained from autopsies at the Calcutta police morgue have been studied to investigate the reserves of this vitamin in health and disease. It was observed that the average vitamin-A reserve of Indian working-class people was between 7 to 10 μg . per gramme of liver and for the middle class it was about 25 μg . per gramme of liver. These values are considerably lower than those observed for normal persons in other countries. In all the 3 cases of opium poisoning comparatively high reserves were found.

F. B., a Muslim female, aged 35 years, was brought to me by a medical student for examination of her blood and urine. She said she was now putting on weight but to me she appeared thin and pale. She has had three live births and one abortion. The first and the second children are now 22 and 20 years old respectively; the third was an abortion at the seventh month and the fourth died at the age of 7 years. This happened about 6 years ago. Soon after the death of the last child she began to have irregular and scanty menses, and finally once in every 5 to 6 months. She approached a hakim for treatment. Her urine at this time was perfectly normal looking. Soon after she started the treatment she felt palpitation and giddiness. To use her own words she did not feel very certain about herself. Then she had itching of the hands and feet, followed by boils. The quantity of urine also began to be diminished and it was irritating. Next she went to her son who was also a hakim. He prescribed some other medicine which gave rise to intractable diarrhoea. Three months after she started the latter treatment the urine became milky, more so, if she drank milk and ate more meat. During this period she had an attack of urticaria which disappeared after some medication. Some distant relations of hers whom she used to visit occasionally are suffering from elephantiasis.

She attributed all her troubles to scanty menses and on the advice of somebody she took some vaginal douches and an oily substance was introduced into the vagina after each douche. This did her menses no good but oedema of feet extending up to the knees appeared on both sides. She was then admitted in the Osmania General Hospital where her condition was diagnosed as sprue. She was given liver extracts and a preparation called erythrogen. She improved and left the hospital, but her symptoms did not abate entirely.

There was no abnormality with her genital organs except slightly retroverted uterus.

Blood report: red cells—3,500,000 per c.m.m., white cells—7,000 per c.m.m., haemoglobin—60 per cent, colour index—0.9. No abnormal cells present. Malarial parasites not found. Wassermann reaction—negative.

Catheterized urine report on the 15th of April, 1940: Colour yellowish white; turbid in appearance; specific gravity—1014; reaction acid; albumin—present abundant; pus cells and red cells plenty; casts not found; fat globules not seen. After extraction with ether a yellowish substance was obtained which looked like fat but had no greasy feel and chemical reactions for fat with osmotic acid and Sudan III were negative. No sugar was detected with Fehling's or Benedict's reagents. Acetic acid did not remove the haziness of the urine, nor did filtration. Urine ceased to be hazy when proteins were removed by heat or by complete saturation with ammonium sulphate. After destructive distillation of urine no volatile fluid was obtained. After the addition of hydrochloric acid and boiling in water-bath for one hour no crystals were obtained.

Detailed report of the protein present:

1. Heat test positive, does not clear with acetic acid.
2. Nitric acid test positive, does not clear with acetic acid.
3. Half saturation with ammonium sulphate—precipitate formed.

4. Filtrate after half saturation with ammonium sulphate: Heat test negative; nitric acid test negative. Biuret reaction negative with the above and also after boiling.
 5. Biuret reaction positive with urine giving violet colour (not pink). Therefore peptones, proteoses and albumin absent.
 6. Urine gave positive reaction for globulin, tyrosin, tryptophane, phenyl analine, glucosamine, cystein and cystin.
 7. Bence-Jones' protein negative.
- Quantity of proteins present was 0.6 per c.c.t.

Second examination done on 10th October, 1940: Urine clearer but still milky. Condition same as above except that now both albumin and globulin are present, proportion, albumin 0.45, globulin 0.30 per cent.

Third examination on 9th November: uriac clear—specific gravity 1009. Proteins have completely disappeared.

Discussion.—In the literature I have come across a condition which is in some aspects similar to the case described above. It is called 'emulsion albuminuria'. I quote below from *Clinical Diagnosis* by L. Napoleon Boston, Director, Clinical Laboratories, Philadelphia.

'Emulsion albuminuria. Under this caption Cramer has described a unique condition of the urine. In this condition the urine is chylous in appearance, but when placed under the microscope its turbidity is found to be due to a peculiar hazing of the entire field caused by innumerable minute globules of fat. When extracted with ether no fat is to be obtained and the osmotic acid reaction is negative. After the evaporation of the ethereal solution an almost colourless residue results, which in one instance—Coriat's case—emitted an odour of burned sugar. Fehling's solution gives a doubtful reaction, and Nylander's (bismuth) test is negative. There is no formation of an osazone with phenylhydrazin and sodium acetate. No volatile liquid is obtained by destructive distillation (acrolein test). The milkiness of such urine is changed to a mere opalescence upon the addition of a few drops of acetic acid or of potassium hydrate. Dilution of the urine with several times its own volume of water also causes a mere opalescence.'

Urine acidulated with hydrochloric acid and heated upon a water-bath for one hour may deposit a crystalline substance which is probably allantoin. This body appears to be more closely allied to crystalline globulin; the crystals occasionally found in urine containing Bence-Jones' albumose; and also the colloidal solution of metals, where, by electric pulverization of such metals as platinum, silver, and iridium, they become mechanically suspended as fine particles in water or other fluids. The urine partly cleared by dilution or otherwise gives the ordinary reactions for proteins.

Upon boiling, a copious precipitate is obtained; the supernatant liquid first becoming opalescent and eventually clear. Artificial peptic digestion also clears the urine; but it remains milky upon the addition of hydrochloric acid alone.

Microscopy.—The sediment of such urine is likely to contain crystals of uric acid, amorphous urates (few), leukocytes, and in one instance pus and a few erythrocytes were found.'

In acute nephritis and in chronic nephritis with waxy degeneration of the kidneys and in some cases of pneumonia globulin is present in the urine more than albumin. I do not know under what pathological condition a pure globulinuria results. The molecule of globulin is bigger than that of albumin, therefore if it were simply an exudation from engorged capillaries as a result of obstruction in the venous circulation one should get both albumin and globulin. In this

case a cystoscopic examination should have been done but it could not be arranged. Since the condition has now completely disappeared we can assume that either this peculiar urinary condition rarely occurs in sprue and has disappeared after this condition was brought under control or it was due to some irritant drugs acting on the capillaries or tubules of the kidneys or capillaries of the bladder inducing this peculiar leakage. The oedema present was of the passive type, bilateral and symmetrical. There is no history of attacks of lymphangitis. Repeated attempts at blood examination for microfilaria have proved negative and now the condition has completely disappeared. The patient has put on weight, and that pale haggard look is gone. Her periods have also become regular. No particular treatment was adopted after she left the hospital.

Summary.—A case with irregular menses was treated by hakims. She developed a condition which looked like chyluria. She had diarrhoea which was diagnosed and treated as sprue. She left the hospital much improved. Her urine showed a condition of pure globulinuria associated with other blood proteins except albumin. There was no fat in the urine though it looked milky. All her complaints have disappeared without any treatment after she left the hospital.

[Clinically the patient appears to have had chyluria. When the urine contains only lymph, fatty elements may be absent or present only in very small amounts. The first two urine reports of this case show presence of albumin.—EDITOR, I.M.G.]

A CASE OF MALARIAL PSYCHOSIS

By S. K. SARKAR, M.B., B.S.

Assistant Surgeon, B. N. Railway, Dongargarh (C. P.)

ON 25th January, 1940, a young man aged about 16 was brought by his parents to Dongargarh Railway Hospital for treatment. He looked very ill. Temperature was 102°F. He was very restless, and delirious. Skin and tongue were very dry. Teeth had sordes on them. Spleen was enlarged. His bowels had not moved for the last three days and he had not slept at all for the same period. He was completely disoriented about time and place and sometimes could not recognize his parents. The present illness had started on 21st January when he had a slight fever without any ague. The temperature rose and continued without any remission. On 23rd his behaviour became queer. He refused food and drink, became very restless, started talking foolishly to himself, and could not sleep. Ojhas (exorcisers of ghosts) tried their hands, but as there was no improvement he was brought to hospital. He had suffered from fever off and on for about two or three months after which he was quite well for about a month and then the present sickness started.

On admission a soap and water enema was given and later on a tepid sponge. Plenty of water to drink was ordered, but as he was non-co-operative it became very difficult for us to make him drink. He was put on glucose drink as much as he wished and plain alkaline mixture. One-fourth grain of morphia was given at night. He was quiet for about an hour after the morphia injection, but restless for the rest of the night. His mutterings continued. On 26th, his condition was about the same. His temperature rose up to 104°F. A blood smear was examined and it revealed a few malignant tertian rings. Quinine bishydrochloride in the

usual dosage was given intramuscularly. Next morning his temperature was 100°F, he looked better and he was more rational. He was put on quinine sulphate mixture (20 grains a day). On 28th his temperature was normal, and he was quite rational. He was given a seven-day course of quinine sulphate by mouth. The fever stopped except for a slight rise on 29th and the peculiar psychosis never returned. It is interesting to note that, when he became rational, he remembered nothing about his illness. He wondered why he had come to the hospital. There was no history of epilepsy or any mental derangement in this boy, and the family history did not reveal anything. This psychosis could not be due to atebrin therapy as he had never taken any.

Discussion.—I read about another case reported by Francis (1938) from Burma in which a woman was charged of murdering her husband. Her behaviour was queer and she denied the charges before the police, who thought that she was feigning insanity and accordingly referred her to the medical authorities. The doctor discovered malarial parasites in her finger blood and treated her for malaria. She recovered and her psychosis vanished. In that case too, she did not remember any incident which happened during her mental aberration.

Malarial psychosis is rare, but it is well to keep in mind the possibility in the tropics when one sees a case of sudden behaviour-change in a patient who has suffered from malaria before and whose behaviour was quite normal up to the time of the sudden break-down.

My thanks are due to my chief for permission to report this case.

CEREBRAL MALARIA—AN AFEBRILE CASE WITH EPILEPTIFORM CONVULSIONS

By JAGADISH C. BHATTACHARJEE, L.M.P.

Darjeeling Himalayan Railway Hospital, Tindharia, Darjeeling

A NEPALI motor driver, aged 38, was driving the car of a gentleman, who was travelling from Siliguri on the morning of 25th November, 1940. After driving 11 miles, the driver suddenly fainted on his seat. He was dropped by the gentleman at this hospital, but he could not give any history of the case except that the person was a resident of Darjeeling and occasionally stayed at Siliguri (a highly endemic malarious place on the foot of the hills) overnight.

The patient was admitted in a state of complete unconsciousness with pupils contracted, reflexes present and equal on both sides, temperature 98°F., pulse 100, respiration 32, stertorous breathing and froth coming out of the mouth. His limbs were flaccid; the spleen and liver were not enlarged. Hardly was our examination over when the patient had an epileptiform fit, characterized by tonic spasm of the muscles with conjugate deviation of the head and eyes to one side, eyes open, pupils dilated, cornea insensitive, upper extremities flexed and adducted, lower extremities extended and face cyanosed. This stage was followed by clonic spasm, and then complete relaxation occurred. The whole seizure lasted for about three minutes.

Similar fits were at first noticed every 10 to 15 minutes, but gradually the interval became more and more prolonged, the last one occurring a few minutes before death.

Examination of the urine showed no abnormality but blood films showed heavy infection with *Plasmodium falciparum* rings. The patient was given an injection of ten grains of quinine hydrochloride in 20 c.c.m. of glucose solution with adrenalin intravenously but this had no effect on the patient.

He died of exhaustion about six hours after admission. No measures however could stop the convulsive seizures. Both rectal and axillary temperature remained within normal limits throughout.

Points to note are :—(i) Complete absence of fever though malaria parasites were found in the blood. (ii) Persistent epileptiform convulsions.

I am grateful to Dr. S. K. Biswas, medical officer, D.-H. Railway, for his suggestion in the diagnosis of the case, which was confirmed by blood examination later.

A CASE OF DUPLICATION OF THE GENITAL TRACT

By S. N. CHATTERJEE, M.B., B.S. (Lko.).

L.M. (Rotunda), L.R.C.S. (Edin.), F.R.M.S.

Obstetrician and Gynaecologist to Thomason Hospital Medical College, Agra

K., aged 25 years, Hindu, female, was admitted into my wards with the complaints of painful menstruation, dyspareunia and sterility. Her menstrual periods

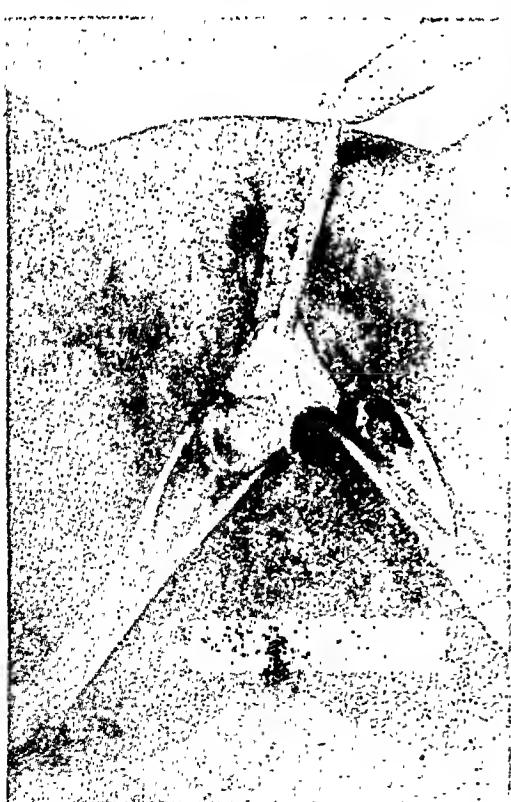

Fig. 1.—Photograph showing the duplication of the vaginal canal. Speculum has been inserted on either side and a catheter in the urethra.

started at the age of 14 years and since then they were regular with a cycle of 27 to 28 days and a duration of 4 to 5 days. Dysmenorrhœa had been

present all along. She was married at the age of 18 years and had the complaint of severe pain during coitus since the very beginning. She had been leading a normal sexual life but she had not conceived.

On general examination the woman was quite healthy. She had no history of any previous disease and nothing abnormal was detected in any of her systems.

On local examination the vulva was normal. The vaginal canal was situated normally and was quite capacious. Hymen was absent. To the left of this opening at the same level was found another opening which was at first missed as it was more or less hidden from the view due to the fact that both the lateral walls were apposed to each other. The passage of a small-sized speculum on this side was very painful to the patient. It was found that the canal extended right through just parallel to the vaginal canal. The vaginal canals were separated by a septum about

Fig. 2.—Skiagram showing the lipiodol injected into the uterine cavity. The free lipiodol is seen in the peritoneal cavity.

1 inch thick. Further examination revealed that there was a separate cervix with a normal external os on each side; they were quite separate from each other. Uterus by bimanual examination was found to be retroverted and small in size.

The patient was detained in the hospital till her menstrual period came on. She was examined by means of a speculum and she was found to be menstruating from both the sides through the cervical canals.

A lipiodol injection was made on either side through the cervix to find out the actual size and character of the uterine cavity. It was found that the uterus was entirely divided by a thick septum. Lipiodol was found in the peritoneal cavity showing that the fallopian tubes attached to either side were patent.

Duplication of the genital tract due to the non-fusion of the Müllerian ducts is a rare condition and the above case is more or less of the *uterus didelphys* type though two uteri separated by a septum could not be made out by bimanual examination.

Acknowledgment.—My thanks are due to Dr. (Mrs.) Dorab, M.B., B.S., for the photograph, Dr. S. Dayal, M.B., B.S., Radiologist, for the skiagram, and Lieut.-Colonel J. C. Bharucha, I.M.S., Principal, Medical College, and Major M. R. Sinclair, I.M.S., Superintendent of Hospital, for permission to publish this case.

MARCH

HOOKWORM INFECTION

HOOKWORM disease is an essentially preventible disease; it is easy to diagnose, easy to cure, and easy to prevent. Yet in India, as well as in many other parts of the world, millions are allowed to suffer from it. One reason for this is that it is not a dramatic and deadly infection like cholera, nor an insidious and deadly one like tuberculosis, but it is none the less a serious debilitating infection that affects whole populations decreasing their working capacity and increasing their susceptibility to other infections over many years. Again, it is not a disease in which a chance infection, by possibly a single organism, sets in train a series of pathological processes that eventually culminate in a serious disturbance in health of short or long duration, but in that the infection—or 'infestation' as some writers prefer to call it to distinguish it from 'infection' where multiplication of the parasite occurs within the host—acts quantitatively and cumulatively, it is more like a slow chemical poison to which the victim must be subjected over a long period of time before the full effect is apparent.

A single pair of hookworms finding their way into the intestine will settle down in the intestinal mucosa, take their negligible ration of blood, and produce a negligible amount of 'toxic' substance; they will live their allotted span of, say, five years, and die, and then their bodies will pass out harmlessly, leaving the host no worse off than when they entered his body. However, what they will have done during their sojourn that is not negligible is to have passed some millions of ova, which, though incapable of harming the host himself at the time, given suitable conditions will develop into an army of larva which, to borrow the technique of the realistic writer, placed end to end would reach from the tea garden in Assam to the company's head office in Leadenhall Street. In actual fact, they will not of course reach anywhere but will remain where they are in the warm damp soil ready to infect the next passer-by.

The individual thus infected with a single pair of worms, or even up to as many as 50 worms, is, in the vast majority of cases, not a medical problem at all, but he is a public health one; he can carry his light load of hookworms without detrimental effect to himself, and, if he is not subjected to further infection, the hookworm load will not increase, but as long as he defæcates indiscriminately in the fields around his house, or where he works, he is scattering infection that will remain a

continuous source of danger to which he and his bare-footed companions will be continually subjected.

Pathogenicity is ultimately a matter of load. It must be granted that there are some subjects who will carry with complete impunity a heavy load of hookworms that would cause serious symptoms in others, and that even a light load may upset a particularly susceptible individual; nevertheless in the long run, where large numbers are concerned—and the hookworm problem only becomes a problem where large numbers are concerned—environmental conditions being equal, the individual with heaviest hookworm load will suffer the worst disabilities, attributable to hookworm infection. Thus, chance infection (using the word to refer to the process of becoming 'infested'), unless this chance infection happens to be a massive one as it has been in rare instances reported in the literature, is unimportant; it is the continuity of the infection and the summation of the infestation that matters.

The hookworm egg develops in the damp soil into a larva and that larva, awaiting its chance (which incidentally is in most circumstances rather less than that the holder of a single ticket has of winning the Derby sweep), settles on and eventually penetrates the skin of a prospective host; after a six-weeks journey through his tissues the larva finds its way into the intestinal canal and becomes a mature worm. There, lying attached to the mucous membrane of her host and sucking his blood, not only to meet her nutritional needs but, wantonly, the female worm passes her eggs, which mixed with the faeces are placed back on the soil wherever the host defæcates; the cycle is thus complete.

This cycle has a number of vulnerable points. The most vulnerable of all is during the egg and larval stages in the soil. In a dry soil, in either a hot or a cold climate, they will not survive for more than a few days, but in a hot damp one they will live for some weeks. It is this fact that determines the varying distribution of hookworm infection in different parts of the country where the habits of the populations are similar. The next two weak points in the cycle are where the ova leave the host and where the larvae enter again; in the first case, if the eggs are not passed into the soil but into a septic tank they will be destroyed, and, in the second, as larvae do not migrate any considerable distance, if nobody passes over the spot where the larvae are waiting, or if feet are protected properly by shoes—ordinarily shoes do not present an impassable barrier—again the cycle will be broken.

The Indian villager usually defæcates in the open ground near his home, in the process he welds both weak points in this cycle, for he scatters the infection on a suitable medium and at the same time becomes further infected himself. On tea estates matters are worse, for

it is common practice for the coolie to defæcate amongst the tea bushes where he or she and the other bare-footed labourers stand for many hours during the day.

At the same time this is a point at which a complete break in the cycle could be effected by the introduction of efficient sanitation, by the provision and the exclusive use of latrines suitable for the particular locality. Once the ova have reached the soil, if nature does not destroy them, man has little chance of doing so; no really successful method of soil sterilization has ever been put into practice. Nor is it a practical measure to attempt to stop infection by the use of shoes. Shoes or boots naturally form some protection, especially in moderately dry weather, but during the rainy season the larvæ will penetrate a comparatively sound pair of boots, even if larvæ-infected mud does not find its way through lace holes.

The last weak point is in the intestinal tracts where the worm can be subjected to the effect of drugs taken by the patient. Attack at this point will only reduce the worm load of the patient temporarily, for, meanwhile, if he is still following his ordinary habits, he will be re-infecting himself all the time. Treatment can only effect a break in the cycle if it is associated with a change of defæating ground, and if it includes the whole population; even then it would have to be repeated in order to catch the larvæ migrating through the tissues, unless it were done at a time of year when no reinfection was taking place.

It must be apparent that the only really efficient measure for the permanent reduction of hookworm disease is the introduction of a system of satisfactory latrines, and this fact should never be lost sight of by sanitarians and employers of labour. The latrine problem is a difficult one, but a beginning must be made and medical officers responsible for the labour in industrial concerns should do everything to make their employers realize the vital importance of making some sort of beginning in the matter of latrine provision. The Factories Act of 1934 has made it compulsory to supply latrines in factories and this has focussed attention on the subject. The form the latrine should take will be dictated by circumstances. The bored-hole latrine (*I. M. G.*, 70, 391) has the advantage of low cost so that individual or household latrines can be installed, with their obvious advantages over communal latrines which one does not need to be fastidious to appreciate. The bored-hole latrine is not, however, suitable in all circumstances nor for all terrains (*I. M. G.*, 76, 126); and in a recent number another useful form of latrine was described (*I. M. G.*, 75, 677).

The whole crux of the matter is the maintenance of the latrines in a cleanly state. If they are not kept clean they will not be used habitually and further they will attract flies and in themselves become an actual danger.

On the other hand, a clean and efficient sanitary system will solve other more serious medical problems, as well as that of hookworm disease.

Anthelmintic drugs.—Millenia-old customs cannot be changed in a day, or even in a year or two, and therefore other methods of controlling hookworm disease must be considered. The alternative is wholesale anthelmintic treatment. As we have indicated above, this deworming has to be very thorough and very complete to effect control of the disease in the whole population, but even with this limitation it is worth attempting, for it will reduce the source of infection which in turn will reduce the chances of re-infection, even if it falls short of achieving a complete disinfestation of the whole population. Further than this, it will confer a considerable benefit on the individuals treated, at the time and for a year or so, until they have again become heavily reinfected.

Twenty-five years ago, the treatment of hookworm infection presented a serious problem; chloroform and thymol, the only specifics, were not very efficient and were extremely expensive. Beta-naphthol was useless in small and dangerous in effective doses. Then oil of chenopodium appeared; it was a more efficient drug and less discriminating, in that it destroyed other helminths, e.g., ascaris, as well as hookworms, but it was variable in its ascaridol content for which constituent it depended both for its efficacy and its toxicity. Oil of chenopodium is now a pharmacopœial drug, its ascaridol content is standardized, and it has taken its place as a useful anthelmintic. Next carbon tetrachloride ($C Cl_4$) was introduced (1921); this is a drug of undoubted efficacy as an anthelmintic and was used by the Rockefeller workers in extensive hookworm campaigns in the American continent. It was given in hundreds of thousands of cases by some workers without causing any ill-effects, but in the hands of others fatalities were reported. Given in large doses it damages both the liver and the kidneys; on rare occasions the same thing occurs when it is given in therapeutic doses. With a drug of this kind absolute safety is essential, as a few fatalities will ruin a treatment campaign. If out of a thousand coolies receiving carbon tetrachloride one fairly healthy man dies during the night following his treatment, which was intended to cure him of an infection he didn't even know that he was suffering from, it is useless to explain to his friends that at least ten of the 999 other coolies would probably have died of some disease acquired through the debility of hookworm infection, had they not been treated, nor is it any consolation to his relatives to know that the man himself would not have died had he not had a drinking bout the night before. This sort of things happened far too frequently on tea gardens and elsewhere in this country for carbon tetrachloride to be received with any enthusiasm for wholesale treatment, and its use-

was limited to conditions where the patient could be treated in hospital and kept under observation for at least 24 hours, or could otherwise be trusted not to take any alcohol.

Then, in 1925, came the closely related drug tetrachlorethylene (C_2Cl_4); no great publicity was given to its début, for meanwhile the attention of the Rockefeller Foundation had been deflected into other channels and the same extensive hookworm campaigns were not being undertaken. It was found that tetrachlorethylene caused no damage to the livers of cats and dogs when administered in large doses even with alcohol (*I. M. G.*, 68, 554). The first clinical trials with this drug did not indicate that it had any special advantages over carbon tetrachloride, but in India the fact that it was a safe drug attracted attention and it has been used very extensively during the last decade (*I. M. G.*, 64, 424; 68, 617; 69, 500; 72, 650; 74, 198; 75, 652).

Meanwhile, further reports have come from America where, though it has been used in hundreds of thousands of cases, only one case of temporary ill-effect has been reported. All these reports indicate that it is at least as good as carbon tetrachloride in its anthelmintic action.

Thymol.—A quarter of a century ago thymol held an important place as an anthelmintic, but its numerous disadvantages, the high cost, the difficulty of administration, its toxicity, a subject to which C. A. Lane devotes over seven pages in his book *Hookworm Infection*, and its relative inefficacy necessitated further research for a better anthelmintic. Thymol was first introduced by Bozzolo in 1879, but its principal advocate was Ashford, a great American helminthologist, so great that when other more efficient anthelmintics were introduced he acknowledged the fact; before his death some eight years ago Ashford came into line with nearly all other American helminthologists and admitted the anthelmintic inferiority of thymol compared with oil of chenopodium, carbon tetrachloride and tetrachlorethylene. In this country, thymol was used extensively, particularly by C. A. Lane, up to twenty years ago, but since then it has been displaced by other, more efficient anthelmintics. To all intents and purposes, as a practical anthelmintic for extensive administration to hookworm-infested populations, thymol died twenty years ago, since when from time to time its ghost has flitted, often rather aggressively, through the pages of our invaluable contemporaries the *Lancet* and the *Tropical Diseases Bulletin*. In order to exorcize this ghost, Maplestone and Mukerji undertook an investigation on the comparative anthelmintic properties of thymol and tetrachlorethylene (*I. M. G.*, 75, 193). The results of this trial were entirely convincing; they showed that a single treatment with thymol left behind 38.1 per cent of *Ancylostoma duodenale* and that after a second treatment with thymol 22.1 per

cent of worms still remained to be removed by other drugs. After a single treatment with tetrachlorethylene only 3.8 per cent of worms were left and after a second treatment none. In the case of *Necator americanus*, both drugs were more successful; the first treatment with thymol left 6.8 per cent of the worms and that with tetrachlorethylene less than one per cent. In a single treatment with thymol only one patient in a series of 25 was cured, and in three others the infestation was reduced to a negligible figure; this left 21 requiring further treatment. With a single treatment with tetrachlorethylene, nine were cured and in 13 others the infestation was reduced to a negligible figure; this left only three requiring further treatment.

Perhaps more significant is the fact that 12 patients received three courses of thymol; the first course removed 679 *A. duodenale*, the second 183, and the third 43; as these patients still showed a significant infestation, thymol was superseded with the result that of 108 worms that had survived three courses of thymol 105 were removed in a single treatment with tetrachlorethylene.

The evidence as it stands to-day seems to indicate that tetrachlorethylene, with its copy-book unblotted over a period of more than ten years, is a safer drug than thymol, with its doubtful past record, but we will not press this point; tetrachlorethylene is at least as safe, it is infinitely more efficacious, it is far cheaper, and it is easier to administer. It seems, therefore, to us that it is quite time that the thymol wraith was finally laid.

Thus, if the control of hookworm disease by disinfestation of the population is to be attempted, tetrachlorethylene is the most satisfactory single drug. This should be given in doses of 4 c.cm. for adults, with correspondingly small doses for children. It is best administered shaken up in two ounces of saturated solution of sodium sulphate, in a single dose; individual doses must be shaken up separately and taken quickly, as the tetrachlorethylene tends to settle very rapidly. A single treatment will effect the removal of 99 per cent of necators and 96 per cent of ancylostomes; a second treatment, say a month later, is obviously indicated where complete disinfestation is the aim, especially if ancylostomes predominate.

Hookworm anaemia.—From the public health point of view, that is all that need be done, but from the point of view of the individual the matter should not be left here. The main disabilities that the individual with hookworm infection suffers are a direct result of the anaemia. This anaemia is produced mainly by the slow but steady draining of the blood of the host by the hookworms attached to the intestinal mucosa, with the resulting exhaustion of iron reserves. The anaemia produced is microcytic and hypochromic, and is a true secondary

anaemia; the toxic action of the hookworm metabolites on the haemopoietic organs is of secondary importance.

On the important subject of the treatment of this anaemia, C. A. Lane in his book *Hookworm Infection* has but two paragraphs, he writes:—'Anaemia is the main secondary feature requiring treatment and iron is the standby'. So far so good, but he goes on 'Nevertheless so long as infection persists the giving of iron is in general useless; and even after disinfestation the haemopoietic organs, particularly the bone marrow, may be in no position to use the iron which is placed at their disposal until arsenic, organic or inorganic, has been added to the medication'. In our opinion there is not the slightest evidence to support such a statement; it is possible by iron administration alone to bring the haemoglobin up to a level well within the normal range of the patient's class, even in a very heavily infected patient (*I. M. G.*, 7f, 1), and there is no foundation for the suggestion that after the removal of the worms there is any depression of haemopoietic function, or that if there were arsenic would remove it.

The remaining paragraph is given, without comment, to complete the quotation. 'There is evidence that traces of copper are necessary. It is unknown whether the carbon tetrachloride which accumulates in the bone marrow after treatment by that drug produces lesions which hinder subsequent recovery from anaemia. The occasional likeness of the blood picture of ankylostomiasis to that of pernicious anaemia indicates on general principles the giving of liver or red marrow; which might perhaps also prove useful in anxiety after carbon tetrachloride administration'! Elsewhere, Lane has severely criticized writers who have laid special emphasis on iron administration in hookworm infection. It is no more irrational to treat the anaemia before removing the worms than it is to give symptomatic treatment in any other disease; frequently such treatment is definitely indicated first, to be followed later by the removal of the cause. This is sometimes the case in severe hookworm anaemia, when, for the comfort of the patient, it may be better to give a course of ferrous sulphate before administering the anthelmintic, though the natural sequence is to remove the majority of the worms by one treatment and then to treat the anaemia.

It is, on the other hand, utterly absurd to remove the worms only and allow the patient to linger on for many months in an anaemic state. Indian dietaries are usually poor, if not actually deficient, in available iron and therefore many people live on the border-line of iron starvation. On such a diet, it will be months, possibly even years, before an individual can make good his iron deficiency and build up a reserve, whereas by suitable treatment this can be achieved within a few weeks. In many cases, the disappointments with the immediate results of a hookworm campaign that have been experienced are due

to this simple fact. The propaganda value of curing the anaemia should not be underrated; the immediate improvement in well-being experienced by the patient and the immediate increase in his working capacity will impress the patient and his employer far more than a post-dated promise of such improvement.

The most convenient and cheapest way to administer iron is in the form of ferrous sulphate tablets, nine grains twice daily. Ferrous iron in the form of a mixture is probably more efficacious; ferrous ammonium sulphate made up with glucose will 'keep' for some weeks, and of this mixture a dose containing twenty grains of the iron salt (equivalent to a little under three grains of metallic iron) should be given twice daily.

We will conclude by saying that no hookworm campaign is complete unless a three-point attack is made, the spread of infection curtailed by provision and habitual use of suitable latrines, the disinfestation of the individuals affected by a suitable anthelmintic, preferably tetrachlorethylene, and the anaemia cured by the administration of iron in large doses. The provision of latrines alone, even if they are used exclusively, will only effect appreciable improvement in the course of a few years but the improvement will be permanent. Deworming alone is often disappointing, unless very thoroughly carried out in the whole population, as it takes many months for the blood to improve sufficiently to be reflected in the clinical picture and meanwhile reinfection will be taking place all the time. Administration of iron alone will produce a marked and immediate improvement in health, but this improvement will disappear within a year or so. Thus, the most permanent results will be obtained by the first measure, the most spectacular by the last, whereas in practice the second is the one that is most frequently put into operation.

(15) Gastric analysis

Introduction.—The gastric juice in the normal individual contains hydrochloric acid, free and in the combined state, the enzymes pepsin and rennin, and the 'intrinsic factor of Castle'. Examination of the aspirated gastric juice, primarily for acidity, but also for the presence of the enzymes, and for other normal and abnormal characters, is known as gastric analysis.

We have included gastric analysis in this series on hæmatological technique, because normal haemopoiesis is to a large extent dependent on normal gastric function, and consequently the knowledge that we obtain from this test is important in both the diagnosis and the treatment of the anaemias.

Achlorhydria or hypochlorhydria are associated with deficient digestion and absorption of a number of food substances. In some cases of microcytic anaemia, achlorhydria is considered to be the main aetiological factor; iron is more easily absorbed from an acid than from an alkaline medium. Free acid is necessary also for ensuring proper peptic digestion (*v.i.*). Further, in the absence of hydrochloric acid, fermenting organisms flourish, causing flatulence, meteorism, and diarrhoea. This mucosal dysfunction leads to a macrocytic anaemia; the anaemia of sprue is often of this type and due to this cause; but neither in sprue nor in nutritional macrocytic anaemia is achlorhydria constant, nor is there any evidence that the 'intrinsic factor' is also absent. Finally, in pernicious anaemia there is complete and constant achylia*, which is associated with the absence of the 'intrinsic factor', though this latter deficiency cannot be demonstrated directly in the laboratory.

In practically all cases of anaemia associated with achlorhydria or hypochlorhydria, the giving of dilute hydrochloric acid, alone or with pepsin, will be beneficial, and may in fact constitute an important part of the treatment.

Methods : Gastric analysis can be done by either of the following methods :—

(i) Single examination : This is an old method and is almost obsolete now. In this method, after complete evacuation of the fasting juice, an Ewald meal, consisting of bread and water, is given to the patient and the stomach contents withdrawn again after one hour.

(ii) Fractional analysis of Rehfuss : In this method, after complete evacuation of the fasting juice, a suitable test meal is given to the patient; small samples, about 10 c.cm., of the gastric fluid are drawn off every 15 minutes up to 2½ to 3 hours.

Fractional gastric analysis gives valuable information as to the motility and secretory function of the stomach. This method is followed by us in the investigation of all cases of anaemia in the hospital and in many of the cases attending the anaemia outdoor clinic.

* The following terms are in common use for the different stages of gastric deficiency :—

Achlorhydria	= absence of free hydrochloric acid during an ordinary test meal, but with response to histamine.
Complete achlorhydria	= absence of free acid even after histamine injection.
Achylia	= absence of free acid and the gastric enzymes, even after histamine.

In the course of the fractional gastric analysis, an injection of 0.5 mg. of histamine is given one hour after the test meal to the patients who fail to show any free acid in any of the previous specimens.

Apparatus required

- (i) Rehfuss' or Ryle's tube, or any suitable modification (*vide figure 1*). These are hollow tubes made of good rubber. They are about 32 inches long with an internal diameter of about 1/8th inch. One end of the tube is open, while the other, the tip, ends in an olive-shaped bulbous protuberance filled with metal to weight it and keep it rigid. There are holes in the rubber at or near the tip for the passage of the gastric juice

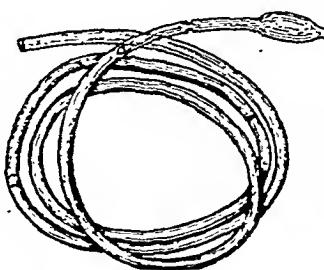

Fig. 1.

through the tube. The distance up to which the tube has to be passed in shown by a mark near the open end, about 20 to 22 inches from the tip.

Before use the tube is sterilized by boiling water, and is kept coiled up in a sterilized petri dish until required.

- (ii) Record syringes 10 c.cm. and 1 c.cm.
- (iii) Twenty-five c.cm. burette graduated in 1/10th of a c.cm., with a stand.
- (iv) Twelve labelled test-tubes in a rack, plus a few extra tubes.
- (v) Capillary pipettes with teats.
- (vi) Small glass funnel.
- (vii) Porcelain dishes—3.
- (viii) Glass rods—3.
- (ix) Centrifuge machine.
- (x) Slides.
- (xi) Microscope.

Chemicals required

- (i) One per cent of cocaine, or a suitable substitute.
- (ii) Seven per cent alcohol 100 c.cm.
- (iii) N/10 sodium hydroxide.
- (iv) Dimethyl-amido-azobenzene (0.5 per cent in 95 per cent alcohol (Töpfer's reagent).
- (v) Phenolphthalein 1 per cent in alcohol.
- (vi) Histamine—0.5 mg. in 0.5 c.cm. sterilized distilled water.
- (vii) Adrenaline chloride solution, 1 in 1,000, for injection.
- (viii) Sulphur powder.
- (ix) Benzidine.
- (x) Glacial acetic acid.
- (xi) Hydrogen peroxide.
- (xii) Pepsin.
- (xiii) Mett's albumin tubes (*v.i.*).
- (xiv) Dilute hydrochloric acid.
- (xv) Fresh milk.
- (xvi) Lugol's iodine solution.

Routine procedure

The following is our usual procedure in carrying out a fractional gastric analysis.

A. Preparation of the patient

On the previous night, the patient has his usual meal at 8 p.m., and at 10 p.m. he is given 4 charcoal tablets with a glass of milk. The next morning he is not allowed any food or drink before the test is finished. Indian patients

must be warned not to chew any *pan*, as it may impart a red colour, which might be mistaken for blood, to the gastric juice.

Before introducing the tube, in very sensitive patients, the nasal mucous membrane and the posterior part of the pharynx may be sprayed or swabbed with one per cent solution of cocaine, or with a suitable substitute.

B. Introducing the tube

(i) Through the mouth : With the patient in a comfortable position, sitting if possible, but the test can be done with the patient lying down; the tip of the tube is placed on the posterior portion of the dorsum of the tongue and allowed to drop slowly backwards and downwards. When the tip strikes the posterior pharynx, the patient is instructed to make swallowing movements and the tip will then pass into the oesophagus. The patient should be told to continue to swallow slowly, when the tube will gradually descend until the end has reached the fundus of the stomach; the mark on the tube gives an approximate indication of when this point is reached.

(ii) Introducing through the nose : With a little practice, the introduction of the tube through the nose is much easier than through the mouth and can be carried out even in the most sensitive patient. The tip of the tube is introduced into one of the nasal orifices and gently pushed through the nose until it reaches the posterior wall of the pharynx. The patient is now told to make swallowing movements while the tube is pushed gently down until it reaches the fundus of the stomach.

Some obstruction may be felt in passing the tube through the nose; this is easily overcome by a little manipulation, but if the resistance is great the tube must be taken out and introduced through the other nasal orifice, as not infrequently the septum is deviated to one side.

C. Drawing out the contents of the fasting stomach

When the tube has been introduced up to the required distance, introduce the nozzle of a 10 c.cm. syringe into the tube, with the piston drawn out; push down the piston so that the air in the syringe is forced through the tube, to dislodge any mucus or food debris that may be blocking it at its distal end; then aspirate the contents of the fasting stomach. If there be any difficulty in getting the juice, vary the position of the tube in the stomach by drawing it out or pushing it in, and/or by forcing more air through the tube.

Rarely, difficulty in obtaining juice may be due to contraction of the gastric muscles, which may be difficult to overcome. An attempt should be made to draw out all the fluid of the fasting stomach by altering the position of the tube in the stomach, by putting the patient in different postures, and by applying a little

pressure to the stomach from outside. The contents of the stomach are placed in the test-tubes previously labelled.

After complete evacuation of the stomach contents the test meal is given to the patients with the tube *in situ*.

D. Test meals

An ideal test meal is obviously one that bears a close similarity to the ordinary diet of the patient, but, for many reasons, it is not possible to give such a test meal. Various test meals have been advocated, but here we shall describe only two with which we have had personal experience.

(i) Gruel test meal : In making this we have always used Quaker oats, but any form of prepared oats can be used, and in this country some workers prefer to use a rice gruel. Take a tablespoonful of Quaker oats in two pints of water, add a pinch of salt, boil down to a pint, and strain through fine muslin. This meal does not contain any lactic acid and is thus almost an ideal test meal, but, with the tube *in situ*, it becomes very difficult and sometimes impossible to swallow such a large quantity of thick gruel.

(ii) Alcohol test meal : One hundred c.cm. of 7 per cent alcohol is used for this meal. The measured quantity of alcohol is placed in a beaker from which it is drawn up into a syringe and introduced into the stomach through the tube—the process is repeated until the whole amount has been introduced.

This meal is very easy to administer, while the fluid that is subsequently withdrawn is almost clear; this allows of easy titration for acidimetry.

E. Withdrawal of post-prandial specimen

Note the time when the test meal is given, aspirate with a syringe about 10 c.cm. of gastric contents every 15 minutes up to 2½ or 3 hours. The specimens are kept in labelled test-tubes until the time of examination.

Histamine.—As the fasting and post-prandial juices are withdrawn, they are examined for the presence of free hydrochloric acid by the bedside.

Take one c.cm. of the gastric juice in a small test-tube, add a small drop of Töpfer's reagent. Note the colour—red or orange colour indicates the presence of free hydrochloric acid and further bedside examination of subsequent specimens is not necessary.

If free hydrochloric acid is not present in the fasting juice and in the first four post-prandial specimens, an injection of 0.5 mg. of histamine is given and the procedure of withdrawing samples is continued as before. A little flushing of the face is seen after injection of histamine, and occasionally the patient may complain of palpitations which generally pass off quickly.

In the event of the patient becoming distressed by these symptoms, an injection of 0.5 c.cm. adrenalin chloride should be given; this will give instantaneous relief.

Examination of gastric contents

A. Macroscopic examination.

(a) In the fasting juice.

- (i) Amount : measure and note the amount. Normally 20 to 25 c.cm. are found. Marked increase over 50 c.cm. suggests hypo-motility, obstruction, or hypersecretion.
- (ii) Odour : normally it has no striking odour. An offensive odour suggests cancer, and a sour odour fermentation.
- (iii) Remnants of food or charcoal : normally no food remnants or charcoal are found after 10 hours' interval. The presence of food remnants or charcoal particles suggests hypo-motility, pyloric obstruction, or ptosis.

(b) In the fasting juice and in the post-prandial specimens.

- (iv) Mucus in large quantity in the fasting juice, and in many of the later post-prandial specimens, indicates catarrhal gastritis.
- (v) Bile : traces of recently regurgitated lemon-yellow bile may be seen in a few specimens and are usually due to retching caused by the introduction of the tube. A large quantity of turbid green bile in the fasting and in any of the early post-prandial samples is almost always pathological.
- (vi) Blood : macroscopic examination for blood gives more valuable information than the chemical examination. Flecks of fresh blood are usually the result of trauma in passing the tube, while large quantities of fresh blood in any specimen would indicate varices, erosions, or even malignant ulceration of the œsophagus. Blood from gastric ulcer or carcinoma of the stomach is changed to brown acid haematin by the acid in the stomach juices; it is found most frequently in the fasting juice, but it may be found also in any post-prandial specimen.

B. Chemical examinations.

(i) Acidimetry.

Place 5 or 10 c.cm. of clear gastric contents in a shallow porcelain dish. If there be an excess of mucus in any specimen, filter the gastric juice through a plug of cotton wool to remove the mucus; this will then allow of easy titration.

Add a drop of Töpfer's reagent to the gastric juice in the porcelain dish, the presence of free hydrochloric acid will be indicated by the red or orange colour of the juice.

(a) Estimation of free hydrochloric acid.

Titrate with N/10 sodium hydroxide until the red or orange colour is discharged : this is done as follows :—

Fill a graduated 25 c.cm. burette with N/10 NaOH up to the zero mark. With one hand regulate the flow of NaOH and allow it to fall drop by drop from the burette into the porcelain dish; stir all the time with a clean glass rod with the other hand. The end point will be shown by a brownish and not a yellow colour. Take the reading of the burette, the difference between the two readings (the first should be zero) gives the amount of NaOH that was required to neutralize 5 or 10 c.cm. of gastric juice.

In clinical work the result is always expressed as the number of cubic centimetres of N/10 NaOH which would be required to neutralize 100 c.cm. of the gastric juice, each cubic centimetre representing one degree of acidity. So, the number of degrees of acidity is calculated by multiplying the number of cubic centimetres of N/10 NaOH by 10, if 10 cubic centimetres of gastric juice was used, or by 20, if 5 c.cm. of gastric juice was used.

The result may be expressed in grammes of hydrochloric acid by multiplying the number of degrees of acidity by 0.00365 (an easy way to remember this is that 365 is the number of days in the year, the last figure—5—indicating the number of decimal places).

*Example.—*If 10 c.cm. of gastric juice was taken and if the end point was reached when 2.3 c.cm. of N/10 NaOH had been added, the degree of acidity is $2.3 \times 10 = 23$.

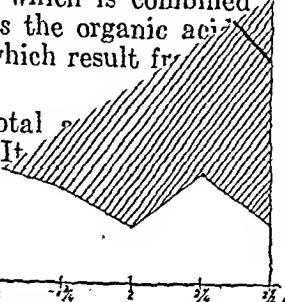

And in terms of hydrochloric acid $23 \times 0.00365 = 0.08395$ g. of hydrochloric acid.

(b) Estimation of total acid.

After the estimation of free hydrochloric acid, or if there be no free HCl at all, 1 or 2 drops of phenolphthalein (1 per cent solution in alcohol) is added as an indicator and the titration with N/10 NaOH is continued until the development of a permanent faint red colour.

The third reading minus the first reading (zero in this case) multiplied by 10, if 10 c.cm. was taken, or 20, if 5 c.cm. was taken, gives the degree of total acid.

The total acidity is made up of free HCl together with the HCl which is combined with protein and mucus, plus the organic acids such as lactic and butyric, which result from fermentation.

The estimation of total acid is of practical importance. It is about 10 degrees higher than the degree of marked lactic acid when it may be present. 

YELLOW FEVER*

By L. EVERARD NAPIER, F.R.C.P. (Lond.)
*Professor of Tropical Medicine, Calcutta School of
 Tropical Medicine*

Definition.—Yellow fever is an acute specific fever of varying severity, but in its most characteristic manifestation of great intensity, and associated with toxic jaundice, caused by a filtrable virus, with a limited tropical distribution, in its urban, epidemic and endemic forms transmitted from man to man by stegomyia mosquitoes, and in its jungle or sporadic form transmitted from its jungle reservoir to man by other means.

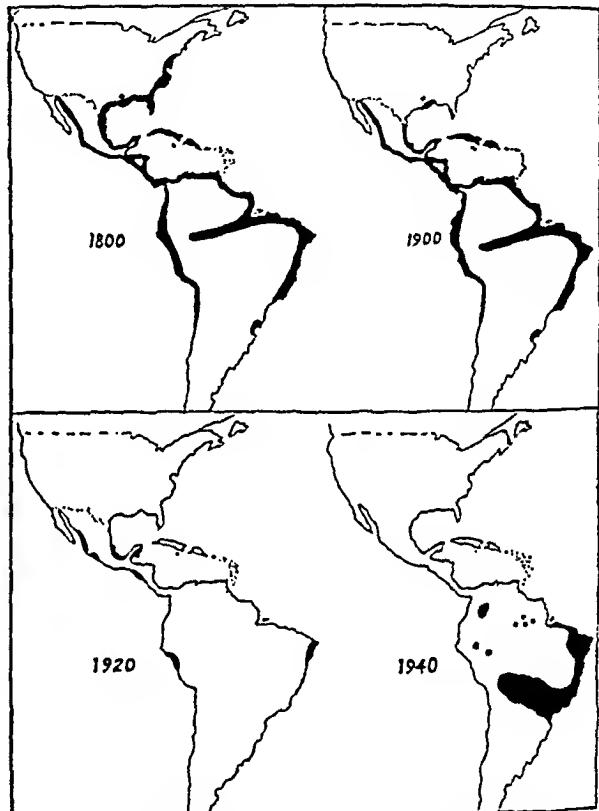

Introduction.—The importance of yellow fever to India and countries further east lies in the fact that, though the disease has up to the present never appeared in these countries, there seems to be no explainable reason why it should not invade them at some, near or distant, future date. The history of this disease shows that it is capable of geographical extension, and, in the American continent, from time to time it has invaded countries which were previously immune. In India, the stage is apparently set for an explosive epidemic should the virus ever be let loose here. It is therefore essential that we in this country should take every precaution to prevent this catastrophe and, if this invasion ever occurs, we should be ready to deal promptly with any isolated case that appears, in the hope that we may stamp out the disease before it gets a firm footing.

In this matter India has not only herself to consider, but she has a special mission in being in the front line of the defence of the rest of Asia; she has not only her hundreds of millions of inhabitants to protect, but the thousands of millions in China and the Far East, for, if yellow fever were to gain an effective hold in this country, it is almost inevitable that it would sweep through the rest of tropical Asia, and in these sanitarily backward countries there would be little hope of controlling it until it had run its course and decimated the populations of this and other eastern tropical countries.

Whilst yellow fever is a disease that has from time to time extended its domain, it is, on the

other hand, one that has been very effectively controlled in many countries where it was firmly established and had become a serious menace to the community. Yellow fever has always been held up as an example of how, medical research having shown the way, sanitary organization has put into effect measures that have been brilliantly successful; these measures were so successful that at one time the hope was cherished that eventually man might completely triumph over this disease and finally banish it from the world. However, recent investigations

Chart demonstrating three phases in the history of yellow fever in the American continent

Between 1800 and 1900 the disease disappeared largely from the United States as a result of general sanitary improvement.

The complete disappearance from the United States and the reduction in Central and South America between 1900 and 1920 was due to the application of the knowledge that the mosquito *Aedes aegypti* was the main transmitter, and to measures directed against this insect.

The apparent extension of the areas involved between 1920 and 1940 does not indicate any real increase in yellow fever but is due to a better knowledge of the true incidence of the disease, gained by extensive employment of the viscerotome and the mouse-protection test, and to the recognition of the 'jungle form' of the disease.

have brought to light facts which show that this hope is vain. The discovery of the 'jungle' form of yellow fever, the virus of which, if not identical with that of the classical yellow fever, is capable of urbanization, has shown that there is a reservoir of yellow fever which may be limitless and over which man may never be able to exercise effective control.

India's supposed safeguards.—It was at one time suggested that there are probably minor differences in the aëdes mosquitoes of this country which make them incapable of transmitting yellow fever; this has been shown not to be the case for aëdes collected in this country have been used in transmission experiments and have been shown to be capable of transmitting the infection. A second hope, namely, that dengue, or some other similar widespread infection, might have produced immunity to yellow fever in our populations, has also been shattered by the discovery that, of the many hundreds of samples of blood collected in various parts of India, none showed any evidence of immunity. We are thus thrown back on the vague hope that, as yellow fever has not appeared hitherto, there must be an unknown factor, some special local condition, which prevents its gaining a footing.

It is not necessary to introduce this 'unknown factor', for the explanation may be that the virus has never arrived in this country, either in an infected individual or in a transmitting mosquito, but, because this has not happened in the past, there is unfortunately no guarantee that it will not happen now or at some future date. This danger is vastly increased by the enhanced speed of transport generally, and particularly by the increase in aerial communications between the yellow-fever areas and the rest of the world. The only safeguard then is increased watchfulness to prevent either an infectious patient or an infected mosquito from arriving in this country; the measures that are in operation to effect this will be described below.

History.—There is evidence that the disease has existed on the American continent from the time of Columbus; a serious epidemic is reported as early as 1493 in San Domingo. There are many early references to a disease that was undoubtedly yellow fever, from this date onwards, and in the eighteenth century it was so well known that quarantine regulations were introduced in connexion with it. It was endemic over a much wider area in earlier days, but it had disappeared from many old endemic areas, even before the exact mode of transmission was known, presumably as a result of the introduction of general sanitary measures. In America, epidemics were reported as far north as New York and Philadelphia, but during the last fifty years only one epidemic of any importance, that of New Orleans in 1905, has occurred in the United States. In its eastern sphere, it was apparently rife in Spain, including Gibraltar, in the Canary Islands, and all along the west African coast. The disease played an important part in naval and military history: in the sixteenth century Drake's fleet was badly infected after calling at West Coast and Spanish ports, and in 1800 a Napoleonic army that landed in the West Indies was almost completely destroyed by yellow fever.

In 1881, Carlos Finlay, a Cuban of Anglo-French parentage, suggested that the disease might be transmitted from man to man by mosquitoes and carried out experiments to demonstrate this. However, this means of transmission was not generally accepted until the historical experiments were carried out in 1900 by the American yellow fever commission consisting of Walter Reed, James Carroll, Jesse Lazear, and Aristides Agramonte. They demonstrated the aëdes transmission, and further showed that yellow fever was not transmitted by contact or other means. Lazear died of yellow fever and Carroll, though infected in an experiment by the bite of a mosquito, developed yellow fever but recovered. As a result of these observations, control measures were instituted against aëdes mosquitoes in Central and South America, and by 1924 the incidence of the disease had been reduced almost to vanishing point.

The next phase of research work dealt with the causative organism. Many organisms were isolated from patients and presented as the cause of yellow fever, but the classical mistake of Noguchi is the only one worth recording, as Professor Noguchi was a brilliant worker who was led down the wrong path by a clinical mistake—not his own, for he was not a doctor. He isolated a leptospira from cases presented to him as yellow fever, and named it *Leptospira icterooides*. It was in fact *Leptospira ictero-hæmorrhagiae*, the causative organism of Weil's disease, which was the disease that these patients were really suffering from. Noguchi died of yellow fever whilst carrying out experiments in West Africa where, dealing now with true yellow fever, he had entirely failed to confirm his earlier findings—a tragic sequel to perhaps the first mistake of a brilliant investigator.

Meanwhile, Adrian Stokes (who later died of yellow fever), Bauer, and Hudson infected Indian monkeys with yellow fever by means of blood filtrates of patients, and further demonstrated that very small quantities of the serum of yellow fever convalescents protected a monkey.

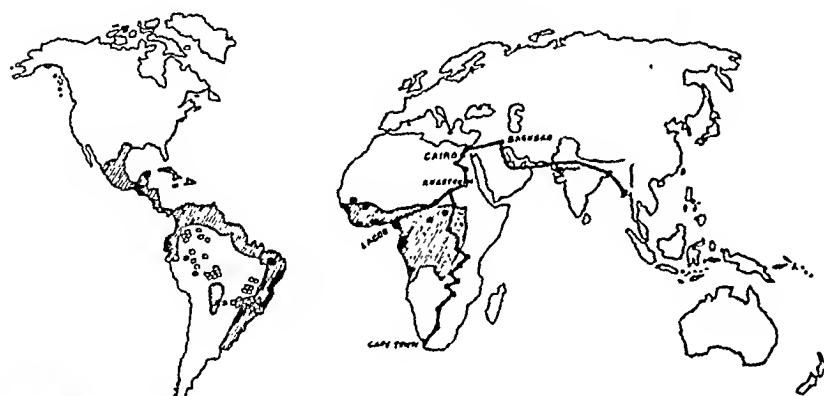

Hindle in 1928 suggested prophylactic inoculation, and Sawyer in 1932 introduced sero-vaccination, which consisted in giving an emulsion of an infected organ in combination with convalescent serum; the latter prevented the development of the disease, but allowed antibodies to develop. In 1930 Max Theiler produced a neurotropic virus, and by 1934 vaccination with neurotropic virus plus immune serum was a well-established method of yellow fever control. More recently, Findlay, McCallum and others grew the virus *in vitro* on chorio-allantoic chick membrane from which nerve tissue had been removed, and produced a virus that had lost not only its viscerotropic but also its neurotropic, whilst still retaining its antigenic properties. With this virus,

vaccinations, probably numbering millions, have now been carried out.

Other recent advances have been in connection with the transmission of yellow fever. *Aëdes aegypti* was at first the only mosquito incriminated; later, other *aëdes* were shown to be potential transmitters; then followed the discovery of 'jungle' yellow fever, with its tremendous implications: jungle mosquitoes, notably *Hæmogogus capricorni*, were incriminated as transmitters, with some jungle animal, possibly monkeys, as the reservoir of the virus.

Geographical distribution.—Yellow fever is confined almost entirely to the tropics. Most

Distribution of yellow fever.

- Endemic at present day.
 - ▨ Past and potential areas of yellow fever as shown by the mouse-protection test.
 - Distribution of 'jungle yellow fever' in South America.
 - ◆ Air routes.

of the endemic areas are on the Atlantic seaboard, though in South and Central America some parts of the Pacific coast are included, and in Africa it extends from the west coast for some thousands of miles inland.

In the American continent, the coastal areas from Mexico in the north, throughout the countries of central and down to the east coast of South America, almost as far as Buenos Aires, all the islands of the West Indies, and on the west coast as far south as Ecuador are all endemic areas, and recently a few foci have been found in Bolivia.

In Africa, it occurs on the west coast from Senegal down to Angola, and inland as far east as the Anglo-Egyptian Sudan, and even into Abyssinia. There are no endemic areas on the east coast of Africa, nor anywhere in Asia.

Aetiology.—The virus. The disease is caused by a filtrable virus, of the size of about 18 to $2^7 \mu\mu$: it is killed at 60° to $65^\circ\text{C}.$, but survives freezing *in vacuo* for many months. It also withstands the action of some strong disinfectants, such as phenol 1 in 150 at $30^\circ\text{C}.$, but is inactivated by the photodynamic action of methylene blue—1 in 100,000. The virus

may be, (i) viscerotropic (or pantropic)—as in the patient with yellow fever or in animals inoculated subcutaneously or intra-viscerally from such a patient, (ii) neurotropic—after serial inoculation in mouse brain, or (iii) free from any organotropism—after serial cultivation on nerve-free chorio-allantoic membrane. There is evidence that the neurotropic virus can revert to the viscerotropic phase in certain conditions, but there is no evidence that egg-grown virus can re-acquire its viscero- or neurotropic tendency.

Transmission.—Infection is very easily acquired in the laboratory and many workers have become infected by contact with the blood of a patient or with infectious morbid material from experimental animals.

The mosquito *Aedes aegypti* is the important transmitter of the urban form of yellow fever from man to man; other *aedes* have been shown to transmit it under laboratory conditions. The mosquito becomes infected if it bites a patient during the first three days of the disease; the virus develops in the mosquito for some days before the latter becomes infectious, the

Latent period becomes infectious, the time varying between four and eighteen days according to the temperature at which the mosquito is kept; under natural conditions in the endemic areas, the latent period is about nine days, and from this time onwards the mosquito may be infectious.

The method of transmission of 'jungle', or sporadic, yellow fever has not been established. Certain jungle species of mosquitoes have been shown to be potential transmitters, but in some places the disease has been acquired in the absence of any mosquitoes. In this form of the disease, transmission to man is probably an accident in an epizootic cycle, the disease being normally transmitted from animal to animal by the same, or some other, insect vector; as the animal reservoir, monkeys are suspected, because in jungles where the disease occurs sporadically monkeys have been shown to carry antibodies in their blood.

Epidemiology.—High temperatures, 75° F. and above, and high humidity favour the spread of the disease. It is therefore confined mainly to coastal areas in the true tropics, and its highest peak of incidence is in the hot damp months of the year. It seldom occurs much above sea level, though it has been reported from San Paulo (2,500 feet).

The incidence of the disease is conditioned by the number of transmitting mosquitoes, the supply of the virus, and the extent of the susceptible material. *Aedes* is a domestic mosquito and seldom flies more than a hundred yards or so from the house. Ships moored 400 yards from the shore are said to be safe, but

this does not take into account visiting craft, such as lighters, which may transport the mosquitoes from the shore. In the urban form, man is the only source of infection and it is probably mild and unrecognized cases of the disease that are the most important source of the virus. The highest concentrations of the transmitter, the source of infection, and susceptible individuals are found in towns, and it is therefore here that the epidemics occur.

Both sexes are equally susceptible, but the disease appears to occur more frequently in men; this applies in particular to the 'jungle' form of the disease which is almost entirely confined to forest workers. In children the disease takes a milder form, but in old people and in alcoholics it is particularly fatal.

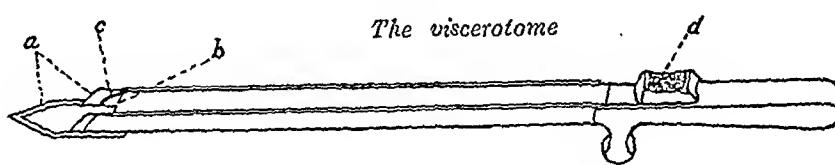

The epidemiology of the disease has recently been studied in two ways, by means of viscerotome surveys and the mouse-protection test (*v.i.*). The viscerotome is an instrument which has been designed for removing pieces of liver without a full post-mortem examination; in all cases of death through an uncertain cause a specimen is taken and examined microscopically (*v.i.*). The mouse-protection test is a test to show the presence of protective antibodies in the blood, and a positive result indicates that the patient has at some time suffered from yellow fever. These two methods have shown the existence of the disease in many parts of South America and Africa where its presence was hitherto not suspected, and the findings have usually been confirmed later by the discovery of clinical cases. In Africa, in certain areas in the Sudan for example, many 'protected' individuals have been discovered, though the disease has never been reported. These have been called 'silent' areas, and, recently, in one such area in the Anglo-Egyptian Sudan, *i.e.*, in the Nuba mountains near Malakal, the 'silence' has been broken by an explosive epidemic. In known endemic areas where the disease has not appeared in epidemic form for many years, children born after the last epidemic have not shown positive protection tests, whereas older children in the same area have provided a large percentage of positives, and finally in Asia and places distant from the yellow-fever areas, no evidence of antibodies has been found in the blood of the inhabitants.

Pathology.—The typical post-mortem picture includes the olive discolouration of the skin (in the fair-skinned races) and of all the organs and tissues, ecchymoses all over the body, especially at pressure points, petechial haemorrhages in the mucous membranes, sometimes extensive haemorrhages into the stomach, muscles, and other tissues, a yellow nutmeg liver, fatty degeneration of the heart, petechial haemorrhages in the brain and occasionally

extensive haemorrhages into the ventricles. Histological examination of sections of the liver shows the characteristic changes that are described below (under *Diagnosis*). In the kidney, there is cloudy swelling and fatty degeneration, more apparent in the convoluted tubules than in the glomeruli, there are haemorrhages into Bowman's capsule and in the cortex, and the tubules are blocked with epithelial debris. The spleen shows few macroscopical changes, but microscopically there is evidence of endothelial proliferation at the expense of the lymphoid tissue.

The pathology in the jungle form of yellow fever is apparently identical with that of the classical form.

These changes readily explain the diffuse haemorrhages, the toxic jaundice, the albuminuria and the eventual anuria.

- a. Cutting edges for introducing viscerotome.
- b. Sliding guillotine blade.
- c. Groove for sliding guillotine blade.
- d. Thumb grip for closing the sliding guillotine blade.

Symptomatology

Incubation period.—This is usually from two to six days, but instances where the interval was as long as twelve days have been reported.

The onset.—In the typical severe case of yellow fever the onset is sudden, with fever and possibly rigor, and a rapid, full and bounding pulse, very severe frontal headaches with pains in the eyeballs and photophobia, pains all over the body but particularly in the loins and bones, an intense burning sensation and dryness of the skin, a furred sharp-pointed tongue with a pink tip and edges, a red and swollen face with the eyes bloodshot and 'beady', anorexia, and severe prostration. In the milder form the onset is more insidious with milder symptoms of the same nature.

The fever.—The temperature rises sharply, reaching 103°F. or so in 24 hours and remains high for three or four days; it then falls, usually rather rapidly and may become sub-normal for 24 hours—the 'period of calm', but it may rise again to 101° or 102°F. for another two or three days or more. It is during the 'period of calm' and the reaction period which follows that death is most likely to occur (*vide* charts, p. 174).

The pulse.—This is rapid, full and bounding at first, but tends to fall before the temperature; it may drop to 50 per minute or even lower during the 'period of calm' and it seldom rises beyond the normal level during the second febrile period. The steady pulse with a rising temperature or a falling pulse with a constant temperature constitutes Faget's sign, a point of diagnostic importance.

The skin.—Jaundice appears on the third or fourth day and is progressive—up to a dark brown colour in severe cases. Earlier appearance is a bad prognostic sign. It is naturally associated in severe cases with yellow discolouration of the sclerotics, bile in the urine and a bi-phasic van den Bergh reaction. Petechial haemorrhages may appear and a characteristic erythema of the scrotum or vulva is common. In severe cases large purpuric patches appear.

The urine.—Albumin appears in the urine on the third or fourth day, and is a useful diagnostic sign; in severe and fatal cases it develops earlier. There are usually hyaline casts. Haematuria and the presence of bile have already been mentioned. The urine is often scanty and the concentration of urea and uric acid may be low.

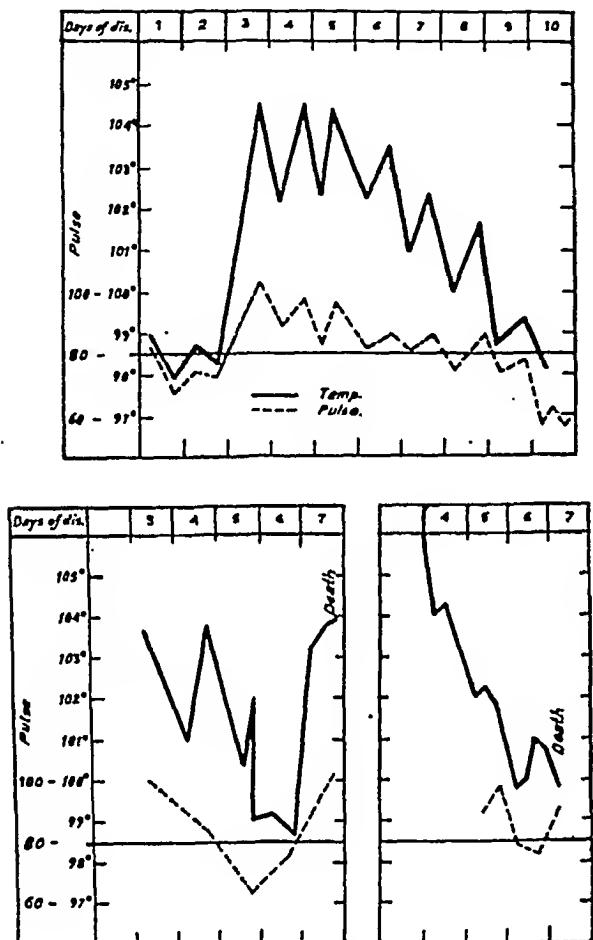

Blood count.—There is a polymorphonuclear leucocytosis during the early stages, and later on a marked leucopenia with a relative increase of large mononuclears.

Diagnosis

There are no simple laboratory tests; the diagnosis must be made mainly on the clinical picture and by a process of exclusion. However, the rhesus monkey is a susceptible animal and can be infected from the blood of the patient during the first three days of the disease. Similarly, intracerebral inoculation into mice will cause an encephalitis within seven to fourteen days, but, as other virus infections cause a similar encephalitis, it is essential that such tests should be controlled by protection tests with known immune (yellow fever) serum. Blood taken for such tests will retain its virulence in the ice-chest for a few days; it is therefore important to take the blood at the earliest possible date in a case of suspected yellow fever, even if there may be some delay in carrying out the test, for antibodies will not develop in the blood in the ice-chest, whilst they will in the circulating blood of the patient.

When in the later stages of the infection antibodies develop, their presence can be demonstrated by a specific test, the mouse-protection test; if the patient's serum, after being mixed with the virus and injected into a mouse, protects that mouse from the effects of the injected virus, this is presumptive evidence that the patient has at some time or another suffered from yellow fever. Although these antibodies appear in the blood at an early date and neutralize the virus in the patient's blood, so that mosquitoes are not usually infected after the third day of the disease, for purposes of the mouse-protection test it is recommended that the blood should not be taken before the twenty-second day at the earliest. This test cannot, however, be done in India, as the introduction into India of yellow fever virus in any form is prohibited by law.

Finally, a post-mortem diagnosis can be made by removing a piece of liver and cutting sections of it. This can be done in the usual way, or, in cases where a full post-mortem examination is not allowed, by the use of the viscerotome, the instrument (*v. s.*) used for removing small pieces of liver without opening the abdomen. The tissue removed is placed in Zenker's fluid and histological sections cut. The histological picture in yellow fever is characteristic. The parenchyma cells of the liver undergo a progressive degeneration. They lose their characteristic

Typical yellow fever charts (adapted).

Other symptoms.—Insomnia and restlessness are constant, but delirium is rare except as a terminal condition. Vomiting may occur with the onset of the fever, as with any high fever, but the characteristic severe vomiting occurs from the third day onwards and may assume a coffee-ground character, the typical 'black vomit' of yellow fever, which is always a bad prognostic sign.

Termination.—Death may occur in the febrile stage from hyperpyrexia with delirium, or in the 'period of calm' and be associated with profuse haemorrhages from all mucous membranes, with black vomit, melena, and haematuria, the patient passing into a comatose state. Death seldom occurs before the third day, or after the eleventh, and if the temperature is down by the seventh day the prognosis is good.

shape, become globular and are surrounded by a clear zone; the cytoplasm undergoes coagulative necrosis, it may become vacuolated, and hyaline eosin-staining areas appear; chromatolysis occurs in the nuclei which are usually rounder and smaller than normal, there is at first margination of the chromatin material, and then red acidophil bodies appear; Küpffer's cells become swollen and degenerated; and, starting in the mid-zonal areas, there is eventually complete disorganization of the normal histological picture of the liver. The full range of changes will not be found in all cases, but the most characteristic finding is the 'Councilman cell', a globular cell in which the nucleus has undergone chromatolysis and contains hyaline acidophil bodies.

Differential diagnosis.—The most constant and prominent symptoms of yellow fever are fever and jaundice, therefore the diseases with which it is most likely to be confused are severe malaria of the 'bilious remittent' type, black-water fever, Weil's disease, and catarrhal jaundice. The milder forms of yellow fever might be confused with relapsing fever, dengue, or influenza.

In the malarial fevers the parasite should be easy to demonstrate, also the jaundice appears earlier and tends to improve; in blackwater fever parasites may not be found, but the haemoglobinuria of this condition should not be mistaken for the haematuria of yellow fever. Similarly, in relapsing fever the spirochæte is usually found in the peripheral blood. The saddle-back temperature of dengue is not unlike that of yellow fever, but the rash when present is characteristic, there is leucopenia, and jaundice does not occur. The only real difficulty that is likely to arise is in differentiating Weil's disease and in this case we have the precedent of Noguchi's classical mistake.

To exclude Weil's disease a specimen of about 10 c.cm. of blood should be obtained as early as possible during the first week of illness. Of this about one cubic centimetre should be inoculated into 10 c.cm. of Vervoort's medium, and 3 c.cm. injected intraperitoneally into a young guinea-pig of 250 grammes weight. The serum from the remaining quantity of blood should be separated with aseptic precautions. Another specimen of 6 c.cm. of blood should be procured at the end of the second week of the disease. The blood culture, the inoculated guinea-pig, and the sera from the two specimens of blood should be forwarded to a laboratory where facilities for examination for leptospiral infection are available. If the case is one of leptospirosis the causal organism will usually grow in the culture medium in ten to fourteen days. Leptospiræ will be found in the peritoneal fluid of the guinea-pig about the seventh day after the infective inoculation, and leptospiral antibodies will be demonstrated in the second specimen of the serum.

If there seems to be a serious possibility that the case is yellow fever the utmost precautions must be taken immediately and the patient kept rigidly under a mosquito net day and night. Also it should be remembered that the virus is present in the patient's blood and is unneutralized by antibodies for at least three and in some cases up to five days, and that therefore every care should be taken to prevent his blood touching anyone's unprotected skin during the process of blood withdrawal.

Immunity.—There is no natural immunity to this infection. Populations in endemic areas subjected to frequent infection acquire a degree of immunity, and the death rate amongst indigenous inhabitants is very much lower than amongst foreigners.

One attack confers almost complete immunity and it is probable that the partial immunity of natives is due to infection in childhood, when the symptoms are usually much milder and may be overlooked. The degree of immunity of a population can be measured by the mouse-protection test. The test is of little value as an individual diagnostic measure, but is a procedure for obtaining retrospective information regarding the past history of a population, *vis-à-vis* yellow fever.

Immunity can be conferred by vaccination; such immunity is effective about fourteen days after the inoculation and lasts for at least two years.

Mouse-protection test.—When a population is to be tested at least 25 adults and 25 children should be chosen at random. Ten to fifteen c.cm. of blood is taken from each and the serum separated. Three c.cm. of the serum to be tested is mixed with 1.5 c.cm. of a 20 per cent emulsion of the brain of a mouse infected with the neurotropic virus. This mixture is then injected intraperitoneally into six mice which have previously had an intracerebral injection of 2 per cent sterile starch solution.

If four or more mice die between five and ten days after the virus inoculation, the test is negative; that is to say there is no evidence of protective substances in the serum tested.

If five survive the test is positive; that is, there is evidence of protective bodies in the serum tested.

An intermediate result is a doubtful result and the test should be repeated. This will necessitate the use of more serum and for this reason some workers advocate taking a larger quantity of blood in the first instance.

The object of including both adults and children is that the results may thus give some indication of the date of the last epidemic visitation, for, if the adults show antibodies but the children none, it may be concluded that the epidemic occurred at least twenty years previously, or prior to the date of birth of the children tested.

Prevention

For the disease to be spread, there are three requirements—the virus, the transmitting mosquito, and the susceptible population. The last two already exist in many parts of India, and only the presence of the virus is necessary to produce an epidemic. Therefore, the first measure of prevention to be considered is the exclusion of this virus from India. Towards this end a very great deal is being done. Air traffic has introduced a new source of danger and it is on this that most attention is now being centred, though other possible channels of entry, e.g., *via* Bombay and other west-coast sea-ports where for many years precautionary measures have been in force, are not being forgotten.

We must first return to Africa. The planes from Lagos on the West Coast, after passing through active yellow-fever areas, join the Cape-to-Cairo route at Khartoum. There was until recently a regular service from Lagos to Khartoum and thence to Cairo. It is thus obvious that a person could get on board a plane at Lagos in the early stages of the incubation period of yellow fever, change at Khartoum, again at Cairo, where he could pick up the regular service plane from Europe to India, and reach Karachi even before symptoms had developed. Further, Malakal, an aerodrome in the Anglo-Egyptian Sudan on the Cape-to-Cairo route, has long been recognized as a 'silent' yellow-fever area, for a large percentage of the population have antibodies in their blood, as shown by the mouse-protection test, and from time to time suspicious cases have been reported. Such 'silent' areas are potential dangers and from here an infected person might arrive in India at an even earlier stage. It was therefore laid down by the International Sanitary Convention for Aerial Navigation that any person wishing to fly from an endemic area shall reside for at least six days in a non-yellow-fever area, if he has not already had yellow fever, and shall obtain a certificate, signed by the aerodrome health officer, to say that he has complied with these requirements, before he embarks.

Notification is cabled from Khartoum to Karachi whenever a passenger from an endemic area leaves for India, so that all necessary precautions may be taken. In addition to this, no planes are allowed to come to Karachi from the endemic or 'silent' areas unless they have passed through either Khartoum or Cairo, which are anti-amaryl aerodromes, that is to say especially equipped for anti-amaryl (anti-yellow-fever) measures, which include local control of *aedes* mosquitoes and disinsectization of the aeroplanes before they leave, and unless they carry a certificate of disinfectization from one of these two places. For this purpose 'pyricide 20', a pyrethrum spray with a kerosene base, has been used, but deskitol, a similar

preparation with a watery base, is safer and almost, if not quite, as effective.

In India, the further precautions that are taken include another thorough spraying of the inside of the plane after the passengers have disembarked before the luggage is taken out, if the disinsectization certificate is not in order, or if there is on board any passenger who does not hold a certificate indicating that it is at least nine days since he was in an endemic area, detention in a special mosquito-proof ward, to which he is conveyed in a mosquito-proof ambulance, of any such passenger, and, finally, prohibition to enter India by air except at Karachi where the organization for carrying out these measures exists*.

The sanitary authorities in India have had a great fight with the international authorities to get these measures enforced in other countries, but they insisted on certain minimum requirements, which were eventually acceded to, and have been in operation for some years without much interference with international air traffic. These precautions do not provide an impassable barrier to the entrance of yellow fever, but they constitute a very effective one and it is probably on them that India's immunity, up to the present, has depended.

Aedes control.—In towns, this is a measure that has been most successfully carried out in America and Africa. *Aedes* is a very local mosquito, easily controlled by general sanitary tidiness around the house, but repeated inspection is usually necessary when one is dealing with an undisciplined population.

Aedes aegypti also transmits dengue and the rapidity with which this infection spreads gives one some idea of how yellow fever would spread if it once gained a footing in India. Special measures are taken at aerodromes and in dock areas to control this species as an extra precaution against yellow fever. In the event of an invasion by yellow fever, *aedes* control would have to be given priority over all other sanitary measures throughout the whole country.

Aedes bites during the day-time, so that suspected yellow-fever patients should be kept night and day under a net, or better still in a mosquito-proof room. Also persons dealing with yellow-fever patients, or with their blood or excreta should be inoculated. The same rule applies to laboratory workers doing experiments with animals and yellow-fever virus. It should perhaps be repeated that in no circumstances is one permitted to import yellow-fever virus into India, for any purpose whatsoever.

Vaccination.—The various stages through which vaccination against yellow fever has gone are indicated above, and the present position of this protective measure is highly satisfactory.

* My thanks are due to Lieutenant-Colonel E. Cotter, the Public Health Commissioner with the Government of India, for certain details regarding the provisions of the International Sanitary Convention and the procedure adopted at Karachi.

The vaccine is made from a strain which was originally a virulent pan-tropic virus that has been passaged some hundreds of times on mouse embryo tissue-culture medium until it completely lost its viscerotropic qualities and became a neurotropic virus: then it was passaged, again some hundreds of times, on chick embryo from which the brain and spinal cord had been removed, so that it lost its neurotropic qualities. The first virus thus made caused no serious trouble, but an appreciable percentage of those inoculated suffered from jaundice; this was possibly due to an accidental contamination with some other virus. The present strain is entirely innocuous; the injection is not followed by any local or general reaction; only one injection is necessary, and it produces an immunity which is protective from the fourteenth day and lasts for a considerable time—there is little diminution in the protective power of the blood at the end of a year, but the vaccine has not been in use for a sufficiently long time for us to say how long the immunity will last.

Many people who are coming out to the East, including some coming to India, get inoculated in London before leaving, but wholesale inoculation has not been practised in India yet, though we believe that large stocks of vaccine are being held in readiness for an outbreak. In Africa, wholesale inoculation is being carried out, especially where there is a danger of the jungle form of yellow fever occurring, for no other measure of control is available for this.

Treatment

There is at present no recognized specific for this disease, so that the treatment is essentially symptomatic.

The patient should be confined to bed throughout the disease and for some days during convalescence. During the height of the fever the diet should be low and consist mainly of lime whey, albumen water and barley water. Plenty of alkaline fluid should be given, sodium citrate or bicarbonate, by mouth, if possible, otherwise per rectum. Glucose should also be given by mouth liberally, and intravenously, a pint of 5 per cent solution, together with five units of insulin.

Early purgation is recommended, $\frac{1}{4}$ grain doses of calomel half-hourly up to $1\frac{1}{2}$ grain, but later purgatives should be avoided.

The following prescription which is designed to reduce acidity is looked upon by some workers as a specific:—

R Liquoris hydrargyri perchloridi ..	m xii
Sodii bicarbonatis ..	gr. vi
Aquam ad ..	5i

Take hourly.

Other treatment is symptomatic:—

Vomiting.—Ten minims of adrenalin (1 in 1,000) by mouth, or $\frac{1}{2}$ grain of cocaine in an ounce of water.

RURAL MEDICAL RELIEF*

By G. G. JOLLY, C.I.E., K.H.P.
LIEUTENANT-GENERAL, I.M.S.

Director-General, Indian Medical Service

THE subject on which I have been asked to address you is rural medical relief. The title sets one reflecting on the scope of the subject. India is predominantly rural: about 90 per cent of her population live in villages and the problem of medical relief to some 350 millions of rural dwellers out of India's total population of 400 millions is essentially the problem of medical relief in India as a whole.

The tahsil headquarters hospital, though usually built in a town, is intended to serve the tahsil; the district headquarters hospital, sited as it is in an urban area, nevertheless serves the rural population more than it does the urban, while the large central teaching hospitals of a province which are located in the great cities, far from being restricted to urban residents, cater extensively for rural dwellers who are attracted by the fame of the hospital and its specialists or referred thereto by practitioners in the rural areas. The proportion of rural to urban patients admitted to the Irwin Hospital,

* Being the substance of the opening address at the Women's Medical Conference held in New Delhi on the 16th December, 1940.

(Continued from previous column)

Black vomit.—Liquor ferri perchloridi m xv, to be repeated.

Hyperpyrexia.—This should be treated by hydrotherapy rather than anti-pyretic drugs.

Restlessness.—Phenobarbitone, grains 1 to 3 by mouth or grain 1 intramuscularly.

Anuria.—Dry cupping to loin, warm colon wash and warm citrate saline bladder wash, in addition to glucose and sodium bicarbonate intravenously.

Stimulants may be required in the later stages, especially during the 'period of calm' when collapse is not infrequent.

Convalescents should be treated cautiously, especially with reference to diet which should be increased very slowly; indiscretion may have serious consequences.

Prognosis.—The disease was at one time considered to be nearly 100 per cent fatal, but later it was realized that a large percentage of the indigenous population enjoyed a high degree of immunity, so that the infection often produced sub-clinical attacks. Even Europeans in Africa suffer from mild attacks which may not be recognized. In most endemic areas about 30 per cent of Europeans suffering from definite clinical attacks of yellow fever die; amongst others the death rate will vary considerably according to circumstances, but in semi-immune populations, it is undoubtedly sometimes a very mild disease, comparable to dengue both in its severity and in its clinical manifestations. In the recent epidemic in the Anglo-Egyptian Sudan, the mortality is reported to be 10 per cent.

New Delhi, is 3 rural to 2 urban. In the Mayo Hospital, Lahore, the percentage of cases from the rural areas is 66.

I would stress this point because there is sometimes a tendency to split medical relief into urban and rural as if they were entirely separate systems, and it is necessary to realize that this is both illogical and impracticable unless economic laws are to be disregarded and an unduly costly and cumbersome system established. Medical relief to any given population requires to be organized in a chain, or rather a series of chains, whose links are located in the various centres of population, large and small, urban and rural, one end of each chain being the general practitioner, the unit, whether in village or town, in immediate contact with the family, while the other end terminates in the central hospital with its exceptional facilities for diagnosis and treatment and its team of specialists.

It is therefore with a realization that the whole range of medical relief in a sub-continent is included in the title of my address that I approach the subject this morning. At the same time, I assume that I am expected to emphasize those aspects of medical relief that are of especial value to the rural dweller and in particular to deal with medical relief agencies sited in the rural areas themselves which comprise the village practitioners and the smaller dispensaries.

There is a dangerous tendency in India to take what appear to be short cuts in medical health work, and to attempt to build from above downwards instead of from below up. These propensities are illustrated by vain endeavours to dispense with the costly foundations of environmental hygiene, such as good water supplies and waste disposal system, and to engage expensive inspecting officers before the rank and file exist for them to inspect.

In the case of medical relief the tendency has been to provide elaborate institutions and specialists at the large centres, contrasting with the most primitive arrangements and practitioners in the villages. The reasons for this are understandable. They are: the small number of qualified medical men, the natural disinclination of these to settle in the villages where life is rough and material reward scanty, and the insistent demand in the towns for better and yet better facilities for medical treatment, supported by the attraction of good fees. Possibly the development that has taken place was inevitable; perhaps it is necessary to fill the towns with medical men before they can overflow to the villages—I don't know.

Of this however I am certain; a sound system as a rural medical relief can only be built upon the foundation of an adequate number of medical practitioners settled in the rural areas. There is no short cut to success here; provincial, district, tahsil hospitals, however well developed, cannot take the place of the general practitioner.

Even rural dispensaries, lavishly distributed as they are in the Punjab, cannot play the part that can only be filled by general practitioners. There is indeed no alternative to the general practitioners' service in the rural areas, whether it is developed as a State service, on a private basis or on the subsidized system. All my experience in the public health and medical services of India has but served to drive home this truth.

In the well-organized village of the future the rural medical practitioner will be able to make a comfortable home and to achieve a reasonable standard of living. Life in the village of the present day however, except in a few favoured spots, is pretty grim and the necessary monetary compensation to lure the young doctor away from the amenities of town life is seldom forthcoming unaided. This is why a number of provinces have tried a system of subsidies, with notable success in Madras where there are some 500 subsidized practitioners settled in the rural areas. In the Punjab I devised a modification of the subsidized practitioner system linked with the co-operative movement. Whenever a co-operative society existed, its members, by paying an extra few annas a month, subject to a total minimum collection of Rs. 50 per mensem, could obtain free medical attendance from a doctor approved by the society, whose remuneration and costs were met in part by the society from these *ad hoc* subscriptions and partly by a subsidy from government. The subsidy is given for specific functions to be performed by the practitioner, including attendance on 'entitled' government servants and medical relief to genuine paupers. Additional duties imposed on the subsidized practitioner would, under this system, be paid for separately. These in the future might include school medical work, vaccination and inoculation and the reporting of vital statistics and epidemic diseases. Such duties should not be imposed at the outset of the scheme or they may easily wreck it. There is a real danger of the 'jack of all trades' who is 'master of none'. Success or failure will depend upon whether the practitioner is a good family doctor inspiring confidence in his diagnosis and treatment and not upon his capability as a sanitary inspector. Duties other than medical relief should not therefore be given in the first instance, or until the practitioner has won for himself a position of trust. On the co-operative medical benefit society side the doctor appointed would be their servant subject to their reasonable rules, and his emoluments would in considerable measure depend upon his popularity with actual and potential society members, since the more people subscribed the higher would be his remuneration.

This system enables government to 'place' medical practitioners in the rural areas at the small cost of Rs. 600 each per annum; it brings modern medical relief within reach of the

villagers at a cost that is not beyond their means, and it guarantees a doctor, settling in a large village or village group, a minimum income of Rs. 100 per mensem to cover his living and professional expenses, an income on which he will not starve and which, if he makes good in his area, he should have little difficulty in doubling before long. It will be appreciated that four annas a month paid by 400 householders with an average family of five gives the doctor a 'panel' of 2,000 and an income over and above his government subsidy of Rs. 100 per month and what he may get in fees from well-to-do persons outside the co-operative society. Naturally the 'medical' benefits received for this small contribution cannot be great but what is needed is a beginning that is financially possible for government, villagers and doctors, that establishes the principle of payment for services received and that holds out prospects of development into an eventual state-aided and controlled system of medical insurance, beneficial to public and practitioner alike.

This scheme, which I have only outlined here, is on trial in the Punjab and its progress is being watched with great interest. If it succeeds the problem of medical relief in the rural areas of India is in my opinion solved. If it fails the failure will put the clock back and be a serious reverse for modern scientific medicine in this country. I am convinced that it can succeed. Modifications and adjustments may require to be made to meet local conditions, but the principles on which the scheme is based I believe to be fundamental and entirely sound.

I come now to the rural dispensary, by which I mean a small permanent self-contained building arranged as an out-patient clinic with, usually, a few beds for emergency cases. Besides the doctor, there are generally a compounder and about two menials, all of whom are housed on the premises. The dispensary costs from Rs. 5,000 to Rs. 10,000 to construct and usually about Rs. 2,500 per annum to maintain. Upon such a rudimentary medical institution, in rural areas devoid of private practitioners from 30,000 to several hundred thousand persons may have to depend for medical relief by modern methods.

Clearly the rural dispensary doctor is an unsatisfactory terminal link to the chain of rural medical relief. Where there is nothing beyond him one would expect him to be completely overwhelmed by demands for urgent casualty treatment alone. Any suggestion that he should take on public health work in addition to medical relief appears merely ludicrous. To demand from him preventive work in an epidemic seems to necessitate a breach of humanity in the neglect of the sick and helpless for the sake of the healthy.

This is all true in a measure. Where, under such circumstances, a dispensary doctor is

efficient, upright, impartial and disinterested, four qualities not easy to obtain together in the conditions of rural dispensary work, he quickly achieves renown and becomes a medical pilgrimage centre famed throughout the district and embarrassed by his popularity. What more often happens is that, if he is reasonably efficient, the villagers nearest his dispensary monopolize his services to the exclusion of the more distant who are obliged to rely upon the vaid and hakim. If, on the other hand, the rural dispensary doctor is below average in efficiency, the chances are that he will become discouraged by the hopelessness of his task, turn lazy, seldom stir from the village in which his dispensary is situated and join the ranks of those public servants who do as little as possible for their pay. This is the explanation of the paradox that in the midst of dire necessity the dispensary sometimes stands half empty. The fault lies with the system rather than with the individual.

What then is the correct rôle of the rural dispensary in the chain of medical relief? I submit that it is to help in the settling of general practitioners in the rural areas and, when they are so established, to act as a 'cottage hospital', serving the area and collaborating with the practitioners in its vicinity. It should in fact be the link between the general practitioners in contact with the families and the district hospitals. With this conception of its rôle in mind it becomes clear that this institution should not be saddled with public health duties. As already noted the general practitioners settled in the villages will in time take on a good deal of this work, but it would be wrong for the rural dispensary doctor to do so. If he is functioning well, he certainly has no time for anything but medical relief. Moreover his assumption of public health duties may postpone the taking up of this work by general practitioners and will certainly delay the development of his dispensary into a cottage hospital. His functions should be clinical and, as soon as there is a sufficient group of general practitioners settled in his vicinity, he should get busy developing the indoor side of his hospital. The rural dispensary, re-oriented as a cottage hospital serving a village group, will as in other countries act as a hospital dépôt or, to use an apt military term, as a casualty clearing station, taking such cases from general practitioners as cannot be treated at home and passing on to the large hospitals those who require special facilities for diagnosis or treatment.

It remains to elaborate the statement, that the rural dispensary should help in the settling of general practitioners in villages. In the Punjab, collateral with the subsidized practitioner scheme there has been developed a system by which the rural dispensary doctor pays regular weekly visits to two or three key villages suitable for the establishment of subsidized practitioners. He holds an out-door

THE ENUMERATION OF THE BLIND IN INDIA*

By E. O'G. KIRWAN, C.I.E., M.Sc., M.B.,
F.R.C.S.I., F.S.M.F.

LIEUTENANT-COLONEL, I.M.S.

Professor of Ophthalmic Surgery, Medical College,
Calcutta

IN foreign countries, India is regarded as a land of blindness. Whether this statement is justified or not at present, it is difficult to prove. It is probably correctly written that there are about one and a half million blind persons in India, and for every one person blind there are three partially blind, out of a total population of 3,53,000,000, whereas the census figures of 1931 show a little over three-fifths of a million blind persons.

So far there has been practically no effort to count the number of blind, although the method is very simple to carry out, i.e., a person is considered blind when he cannot count the fingers of a hand held up in front of his eyes at a distance of one foot. This is the method adopted in Egypt and it was also adopted by the Government of Bengal according to my suggestion in the census of 1931.

The first blind relief association in India was started in the Bombay Presidency by the late Mr. C. C. Henderson, I.C.S., in the year 1913. He received the idea and impetus of starting an association like this from the fact that a child of his own was born blind, and he worked till his death for the noble cause of prevention of blindness in India.

This blind relief association carried out a survey of the blind in some districts of the Bombay Presidency and found—in Nasik district 4.4 per thousand, as against the census figures of 1.74; in Bijapore 2.6 as against 0.7; and in Ratnagiri 1.5 as against 0.7.

Birth of 'A. P. B. B.'

It was felt as far back as 1929 that a society for the prevention of blindness should be started in Bengal. The inaugural meeting was held at

* Read at the Eighth Conference of the All-India Ophthalmological Society held at Bangalore in December 1940.

(Continued from previous page)

clinic there and sees such serious sick cases as time permits in their homes. When he has worked up a connection and the villagers have begun to appreciate his visits, he suggests that they form a medical benefit society, subscribe the minimum Rs. 50 a month qualifying for the government subsidy, and obtain a resident subsidized practitioner. It is hoped in this way to build up around each rural dispensary a small group of subsidized practitioners in touch with and feeding it just as the dispensary, developed into a cottage hospital, will itself feed the larger hospitals.

Government House, Calcutta, in March 1930, under the Chairmanship of the Hon'ble Lady Jackson, the wife of the then Governor of Bengal. In this way the Association for the Prevention of Blindness, Bengal, came into existence and began to function with a strong committee with the Hon'ble Sir George Rankin, then Chief Justice of Bengal, as President.

The first donation of \$500 dollars was received from Mrs. Winifred Holt Mather, Founder-Secretary, National Society for the Prevention of Blindness, New York, U. S. A., who with her husband came to India in connection with the work of prevention of blindness. This gave a big stimulus in starting this association.

A meeting of the ophthalmic surgeons in Bengal was arranged by the honorary secretary, this meeting was held on 1st of December 1930 and a definite programme of work was planned out. From the beginning, one of the great efforts has been to estimate the number of blind persons in Bengal. This was not actually made possible until the association started the first travelling eye dispensary in India at the end of March 1936. There are now four such travelling eye dispensaries of the association touring through the districts of Bengal. Each unit has two medical officers who, in addition to doing preventive and curative work, carry out a survey of the blind in different villages of Bengal.

In the survey of 379 villages of different districts of Bengal from April 1936 to October 1940, 670 completely blind persons out of a total population of 1,84,477, i.e., 196.91 blind per 100,000 have been found, in contrast to 73 per 100,000 according to the census returns of Bengal for 1931. Our findings for the first hundred, second hundred villages and so on are tabulated below :—

TABLE

Number of villages	Population	Blind	Blind per 100,000
1st hundred ..	78,767	306	388.48
2nd hundred ..	154,167	472	306.16
3rd hundred ..	250,747	600	239.28
Up to 379 villages ..	340,240	670	196.91

To get accurate results, medical officers of the travelling eye dispensaries are instructed to obtain the population figures of the villages from the presidents of the union boards and to base their calculations on the figures supplied by them.

A medical officer in company with the circle officer and with the help of the village chowkidars carry out the actual counting of the blind in the different villages. These are probably fairly reliable.

In the campaign for the prevention of blindness, it is most important to gauge the real position of the number of the blind in India. The Association for the Prevention of Blindness, Bengal, is slowly moving in this respect, and, although it will take many years to complete the work throughout the whole of Bengal, it will eventually produce accurate results.

It will be a pity if the enumeration of the blind is left out of the census of 1941 by the

Government of India, the figures, no matter how inaccurate, are valuable and helpful.

Lastly, if other provinces of India follow the example of this association then it may be possible at a future date to find out accurately the total number of blind persons in India.

My thanks are due to Mr. N. R. Mukerjee, B.Com., for helping me in collecting the figures for this article.

Medical News

THE TUBERCULOSIS ASSOCIATION OF INDIA.

Training courses.—Two post-graduate courses in tuberculosis under the auspices of the Tuberculosis Association of India were held in Calcutta and Bombay on the 13th and 15th January, and the duration of these courses were three weeks and one month, respectively. Twenty-four doctors attended the Bombay course and 30 the Calcutta course.

These post-graduate courses are, of course, not intended for specialists, but to meet the requirements of general practitioners who wish to do more for tuberculous patients in their practice, and particularly for such doctors as are prepared to co-operate in tuberculosis schemes.

Tuberculosis institutions.—In performing the opening ceremony of the Tuberculosis Clinic in the Civil Hospital, Bannu, on the 25th of January, His Excellency Sir George Cunningham, Governor of the N.W.F.P., paid a tribute to the great services rendered to the people of India by Her Excellency the Marchioness of Linlithgow by raising funds to combat the ravages of tuberculosis. The Clinic has been built at a cost of Rs. 8,000.

Annual General Meeting of the Tuberculosis Association of India.—The Annual General Meeting of the Association will take place at the Viceroy's House, New Delhi, on the 25th March, 1941, at 6 p.m. It will be open to the members of the Central Association.

Tours.—Dr. C. Frimodt-Möller, C.B.E. (Hon.), Medical Commissioner of the Association, visited Madras from the 5th to 7th January, and gave three lectures to the students of the T.D.D. course instituted by the Madras Government. He also visited Bombay from the 22nd to 24th January and delivered three lectures at the post-graduate course in tuberculosis which has been organized by the Tuberculosis Association of India.

POINTS FROM THE MINUTES OF THE MEETING OF THE UNITED PROVINCES MEDICAL COUNCIL HELD AT LUCKNOW ON 22ND NOVEMBER, 1940

It was resolved unanimously that having very carefully considered the question of the granting of a certificate of proficiency in allopathy to vaids and hakims acquiring diplomas from the Board of Indian Medicine, on the ground that they receive a good deal of training in allopathy also, the Council take the view that unless the curriculum of this board conforms to that laid down by the Indian Medical Council or the State Medical Faculty, both in basic education as well as in clinical and scientific training, the Medical Council cannot agree to the proposal.

With regard to the note appended to the report, the Council considered the note of the standing committee regarding the housing of the Council, its committees and the offices and resolved that a more suitable

building with sufficient accommodation for holding the meetings of the Council, its committees and accommodating its offices be rented from the commencement of the next financial year. As the offices of the Council are combined with the offices of the State Medical Faculty and the Nurses Council, consent of these bodies should be obtained before taking action on this resolution and sharing the expenses.

Resolved that the Government be informed that the Drugs Bill was received when it had been passed into law and therefore there was no time for the members to study it. They therefore request that in important matters, which may be referred to them for opinion, the Council may kindly be allowed sufficient time to study the same.

Resolved unanimously that this Council recommends to the United Provinces Government to consult this Council on the report of the United Provinces Medical Reorganization Committee before it is given effect to.

Resolved *nem. con.* that the consideration of the question of recommending to the Government of India that the Indian Medical Council Act, 1933, be so amended as to provide for a majority of elected members on the Council, be postponed to the next meeting.

Resolved unanimously that this Council recommends to the Provincial Government, and through them to the Government of India, that all medical certificates issued by registered medical practitioners or by civil surgeons or railway medical officers be placed on the same footing and all rules and orders to the contrary be repealed at an early date.

MANUFACTURE OF FISH OILS IN INDIA: AN OLD INDUSTRY REVIVED

At the fourth meeting of the Medical Stores Supply Committee held in New Delhi, the chairman, General G. G. Jolly, director-general, Indian Medical Service, revealed that a flourishing fish-liver oil industry existed in the Madras Presidency 80 years ago. Apparently this flourishing concern was gradually killed by competition in prices.

Medicinal liver oil from the shark and saw-fish is once more being produced in Calicut. It is understood that efforts are also being made by the Governments of Bombay and Bengal and the State of Travancore to manufacture fish oils. Modern research has shown that the use of shark and saw-fish liver oils as a substitute for cod-liver oil is sound practice, since the former are considerably richer in vitamin A than cod-liver oil. Yet long before vitamins were heard of, the medicinal value of shark and saw-fish liver oils was recognized in India where vitamin-A deficiency is widespread.

A modern industry engaged in the production of medicinal fish-liver oil enjoys the advantage that scientific methods for testing and standardizing such oil are available. Investigations about the vitamin content of oil in the Nutrition Research Laboratories, Coonoor, and other laboratories have played an

important part in recent developments. There is an enormous need in India for cheap medicinal products rich in vitamin A and other vitamins.

A Report on the Sea Fish and Fisheries of India and Burma by Surgeon Major Francis Day, Inspector-General of Fisheries, published in 1873, shows that in the sixties of last century there was a considerable production of fish oil on the west coast. For the years 1864-71, the high figure of 3,194,672 pounds with a value of Rs. 2,03,829 is given as the export from Madras alone. This was not medicinal oil, but chiefly sardine oil used for a variety of purposes. But medicinal oil, obtained from the shark and saw-fish, was being

produced simultaneously, apparently mainly for use in India itself. For some years over 5,000 pounds per annum were manufactured, the price ranging from nine annas to Rs. 1-4 per pound. The main centre of production was Calicut, where manufacture was initiated in 1854, the process being under the supervision of the civil surgeon of Malabar.

It is not clear from the report whether medicinal oil was also manufactured in Bombay and Sind. About 1870 the cost of cod-liver oil fell below that of Indian fish-liver oils and apparently the Indian industry languished because it could not compete with the imported product.

Current Topics

Improvements in the Operation of Caesarean Section

By J. L. CAMERON, M.D., F.R.C.S.

(From the *Medical Press and Circular*, Vol. CCIII, 19th June, 1940, p. 514)

CÆSAREAN section, whereby the foetus is removed from the uterus by abdominal section, is one of the oldest of operative measures, but historical evidence of the operation having been performed does not appear until about the fifteenth century, although many stories were told of its performance upon the living woman before this date. Details of the procedure and the results are lacking, but we may surmise that the results for the mother must have been fatal in almost every case, as the undertaking was then conducted without haemostasis or antiseptic precautions.

The first step towards improvement in the operation was doubtless its application to the living woman, and some of the early stories relate that in a few cases the mother survived.

The next advancement, and an extremely important one indeed, is said to have been made by Lebas, who in 1769 attempted to suture the uterine wound. He inserted three stitches, bringing the ends outside the abdomen to provide for their removal later.

Another advance was made in 1877, when Poro of Pavia delivered the child, performed sub-total hysterectomy and exteriorized the uterine stump by suturing it in the abdominal wound. This procedure appears to have considerably lowered the mortality.

In 1907 Frank of Bonn introduced what later became known as the lower segment operation. He also employed a technique whereby the peritoneal cavity was excluded. Selheim, in 1908, further developed the technique of the lower segment operation and demonstrated its advantages.

The greatest strides in technical procedure must, without question, be attributed to the employment of anaesthesia, and to antiseptic and aseptic surgery.

The most up-to-date advancements fall largely into four groups: choice of case, choice of time, choice of technical procedure, and pre- and post-operative management.

Choice of case.—This takes into consideration the indications for the operation. There is still some controversy over the type of case for which operation is indicated, but there appears to be a gradual trend towards a more uniform opinion.

Indications are briefly summarized as follows:

(1) *Cephalo-pelvic disproportion.*—When contraction is extreme, the diameter of the pelvis being less than three inches the indications are absolute, otherwise they are relative.

(2) *Pelvic tumour*, e.g., uterine, especially cervical or low segment fibroid or carcinoma of the cervix, ovarian, vaginal, rectal or parietal growths—or the non-pregnant horn of a bicornuate uterus.

(3) *Malpresentation.*—Breech presentation with extended legs in a primigravida, especially if elderly or

if, as is often the case, there is also some degree of pelvic contraction, is a positive indication.

Oblique presentation may be considered in the same way.

(4) *Ante-partum haemorrhage.*—Central placenta prævia or even the marginal type should be treated by operation when the case is near term if the child is large, the patient elderly, dilatation slow, and especially if contractions are poor or absent.

Accidental haemorrhage is an indication only when uterine contractions are absent.

(5) *Uterine dysfunction.*—(a) Primary uterine inertia. Operation is definitely indicated when uterine pains are very short in duration, ineffectual, tending to cease altogether, and failing to respond to the judicious administration of oxytocic substances.

(b) Contraction ring. Operation is indicated in the case of a viable child when the contraction ring (i) lies entirely below the presenting part, or (ii) is situated high up, grasping the neck or body of the child and when steady, prolonged traction has failed to effect delivery.

(6) *Severe pre-eclamptic toxæmia.*—When this condition is present and increases rather than improves under adequate medical treatment, the patient should be delivered by operation, as the danger of eclampsia is imminent.

When eclamptic fits have started Cæsarean section should never be undertaken, for the death rate in such cases is much higher than when treatment by the conservative methods, now well known and established, is employed.

(7) *Maternal systematic diseases.*—Operation is advisable in certain cases of heart disease with failing compensation, in cases of thyrotoxic goitre with marked tachycardia and pronounced nervous symptoms, in active tuberculosis, and in nephritis with low renal function.

(8) *Funicular prolapse.*—This condition only occurs about once in 300 labours, and, the child being usually dead, operation is seldom performed, but is indicated, as the only means of saving the child's life, when prolapse or expression of the cord occurs early in labour, associated with a small os, and especially when the mother is a primigravida. It must also be remembered that with prolapse of the cord the uterus is already potentially infected.

(9) *Elderly primigravida.*—Cæsarean section should be performed when the mother is over 38 years of age when the cervix dilates slowly or not at all, and especially if there is associated cephalo-pelvic disproportion or any malpresentation.

(10) *Previous Cæsarean section.*—This need only be considered as an indication when the previous operation was of the classical variety.

(11) *Stenosis of the vagina and cervix.*—When this condition is present, operation is clearly indicated.

Choice of time.—The ideal time to operate is before the membranes rupture, before intra-uterine manipulations, such as attempts at version, rotation or forceps

MARCH, 1941]

delivery have been undertaken, and preferably before many vaginal examinations have been made.

If a trial of labour is being made and the membranes rupture, the operation should not be delayed for more than two or three hours.

Choice of operation.—The operations which may be employed are: (1) the classical; (2) low segment, (a) intra-peritoneal, (i) by midline vertical incision, (ii) by transverse incision; (b) extra-peritoneal, or by peritoneal cavity exclusion.

One of the greatest advancements has been the extended improvements in the low segment operation which have done much to diminish maternal mortality due to septic peritonitis, post-operative adherence and obstruction of the bowel, and rupture of the uterine scar during a subsequent pregnancy.

1. THE CLASSICAL OPERATION

This operation is too well known to require any detailed description. It is definitely contra-indicated in any potentially infected case, such as one which has been long in labour, when the waters have been drained away for more than two or three hours, when the cord is prolapsed, when intra-uterine manipulations have been undertaken, or many vaginal examinations made. It is also contra-indicated when there is shock, collapse, or placenta praevia and in tuberculous or cardiac cases.

The chief improvement in the classical procedure, apart from the observance of the contra-indications, is the adequate suture of the uterine wound.

2. LOW SEGMENT OPERATION

(a) Midline vertical incision

Procedure.—Although it renders the operation much easier by enabling the presenting part to gravitate away from the symphysis, bringing the lower segment well into view, the Trendelenburg position is not employed in this procedure as, in that position, liquor and blood tend to gravitate into the peritoneal cavity, increasing the risk of spreading peritonitis.

The vagina is swabbed and the bladder catheterized. The abdomen is opened in the midline for a length of six inches, the lower end being at the symphysis. The edges of the wound are covered with tetra cloths and separated with a self-retaining retractor. Turkish towels, wrung out of hot saline, are packed across the front and sides of the uterus to close off the space and prevent the upward escape of fluid.

The peritoneum, where it is reflected from the front of the uterus, is divided transversely. The bladder is swept off the uterus with gauze mops, and held with a bladder retractor so as to expose the lower segment as far down as possible. The uterus is incised in the midline for five inches, the lower end being well down near the cervix. With a fresh scalpel an incision is started and deepened to about half-way through the muscle and is completed with scissors. The cut vessels are clamped with ring or special wide-jawed forceps and liquor and blood quickly sucked or mopped away.

A hand is inserted and the presenting part lifted vertically upwards through the uterine opening, which can be extended if necessary. The assistant, by pressing strongly upon the fundus uteri through the abdominal wall delivers the child and presses the fundus well downwards. After the cord is clamped and tied, the placenta and membranes are removed, the uterus is inspected and injections of ergometrine and pituitrin made directly into the uterine muscle.

The incision in the uterus is closed with two rows of interrupted stitches, the first uniting the muscle edges by passing in and out superficial to the endometrium. The second stitch oversews the first, heaping up the coapted parts of the muscle to ensure a thick reunion.

All bleeding points are carefully secured with mattress stitches and bleeding from the bladder vessels is arrested with clamp and ligature.

When the extra-peritoneal space is thoroughly dried, the divided edge of the reflected peritoneum is resutured

over the raw area so as to come well above the uterine incision, which is thus completely covered. This suturing is conducted in such a way as to turn the surface of the lower flap of peritoneum against the front of the uterus so that no edge is left exposed.

Clots and blood are removed from the pelvic cavity, and the abdomen is closed in the usual manner.

(ii) Transverse incision

The lower uterine segment is opened by a V-shaped incision, the other steps of the operation being identical with those already described.

(b) Extra-peritoneal procedure

Procedure.—The patient is placed in the Trendelenburg or half-Trendelenburg position. When the peritoneum at the upper aspect of the bladder has been identified and dissected free with the fingers from the cellular tissues and lower uterine segment, it is clamped across with a pair of forceps on each side above the bladder. Another pair of forceps is applied immediately above these across the peritoneum which is divided with scissors. If the peritoneal sac spreads out too widely, a second pair of forceps on each side will have to be applied across its lower end medial to the first pair. A ligature of catgut is tied in the groove made by the two pairs of forceps at the top of the bladder, which is pushed downwards with a swab and held with a bladder retractor, exposing the lower uterine segment. In the upper part of the wound the lower part of the peritoneal sac will temporarily be held closed with four pairs of forceps.

The peritoneum is gently stripped upwards off the uterus with gauze pressure to give a maximum exposure of the lower segment, care being taken not to tear or open the peritoneum. The two layers of the peritoneal sac held by the forceps are now sewn together with a continuous stitch of catgut, the successive pairs of forceps being removed as the stitching proceeds.

The peritoneum is carefully inspected to ensure that no opening is present. If such be found, it is closed with one or two stitches of catgut.

A broad triangular area of the lower uterine segment is now exposed and is opened by a V-shaped incision, the apex being at the lower end near the retracted bladder. The upper ends need not be more than three inches apart and must not be carried too widely for fear of injuring the uterine vessels. If large veins are seen coursing over the surface in this situation they should be underrun with catgut on a round-bodied needle and tied.

The opening in the uterus is outlined with a fresh scalpel which cuts about half-way through the depth of the muscle, the incision being completed with scissors. Care must be taken not to cut the baby's fingers, ears or genitalia. A sitch of catgut is passed on each side of the incision at the apex of the triangle, the ends being left long.

Large bleeding vessels are controlled with light ring forceps or special wide-jawed forceps. Escaping liquor and blood is removed rapidly with a wide bore suction tube or large mops. Occasionally a small opening can be made in the uterus through which the tube is inserted, and the liquor can be removed with a minimum of soiling of the tissues.

The presenting part is lifted with a hand vertically through the opening which, if made as described, is usually ample. If it is found to be inadequate the upper ends of the V-shaped incision can be extended. As the head is lifted up the assistant presses strongly upon the fundus uteri through the abdominal wall. This fundal pressure is the real power which delivers the child, and it also presses the fundus well downwards, promoting contraction and retraction. This method of delivery is a great improvement on the employment of obstetric or scalp forceps.

The cavity of the uterus is inspected to ensure that no fragments of placenta or membrane remain.

At this stage ergometrine and pituitrin are injected directly into the uterine muscle. The discovery and introduction of ergometrine by Chassar Moir must be

regarded as an important improvement, as it induces immediate and prolonged contraction and retraction of the uterine muscles, thus reducing haemorrhage to a minimum.

The uterine incision is closed as in the vertical procedure. The extra-uterine space is thoroughly dried and inspected, and any bleeding point must be secured with a mattress stitch of catgut.

The upper end of the bladder is attached with a stitch of catgut to the united edges of the peritoneal sac, and the abdomen is then closed in the usual way.

When the case is potentially septic, the extra-peritoneal space is thoroughly swabbed with acriflavin and glycerine (1 in 2,000) before the uterus is opened, and again before the rectus sheath is sutured.

The retrovesical-extra-peritoneal space is drained by a tube passed through the lower part of the uterine wound and vagina, or through the abdominal wall.

Disadvantages.—The chief disadvantage of this procedure is that of working in a small space which rapidly becomes filled with blood and liquor amni, greatly reducing visibility. A wide bore suction tube usually overcomes this difficulty.

ALTERNATIVE METHOD

In this procedure the parietal peritoneum is opened transversely just above its attachment to the bladder. The loose reflection of the peritoneum from the front of the uterus on to the bladder is lifted up through this opening and divided transversely. These two incisions are continued until they meet.

The bladder is pushed downwards with gauze mop and held with a retractor.

The peritoneal edges are picked up, stripped upwards as far as possible off the lower uterine segment and the two edges sutured together so as to shut off completely the general cavity.

The remaining steps of the operation are identical with those described above.

IMPROVEMENTS IN ANAESTHESIA

Probably the chief improvement in anaesthesia for Cæsarean section is the more extensive use of local infiltration analgesia.

Novocaine (0.25 per cent) in large quantities is used, infiltration being made under the skin to be incised and also into the subcutaneous tissues and peritoneum. Block anaesthesia of the nerves supplying this zone is also made. Large amounts must be injected into the cellular tissues behind the symphysis pubis, a very sensitive region. Incision must not be made until at least five minutes after the completion of the infiltration, thus allowing time for the anaesthetic to act. Whenever pain is felt operating should cease and the painful zone be lavishly infiltrated.

Local anaesthesia is especially useful in cases of shock, cardiac disease with poor compensation or in a tuberculous case.

Spinal anaesthesia would appear to be almost ideal in that it does not in any way affect the baby; uterine contractions and retractions proceed normally; there is absence of pain and the muscular relaxation is complete. There are, however, precautions which must be taken. It should be avoided when there is pronounced shock and when blood-pressure is low. It must be used in the smallest quantities compatible with the desired effect. The anaesthetized zone should not extend above the umbilicus, and when the Trendelenburg or half-Trendelenburg position is used the anaesthetizing substance must be of lower specific gravity than the cerebro-spinal fluid.

Safe general anaesthetics are nitrous oxide and oxygen, or ether and oxygen. Nitrous oxide has little effect on the child, but does not produce sufficient muscular relaxation to permit the low segment operation to be performed easily. Ether, on the other hand, overcomes this difficulty, but it depresses the respiratory centre of the child, especially when the lower segment operation is performed and more time is consumed.

Cyclopropane is said to have the advantages of both these anaesthetics, but its use may be attended by collapse.

A method much in favour is to induce anaesthesia with nitrous oxide and oxygen and to attain muscular relaxation by the addition of ether after the abdomen is opened. To produce as little effect as possible upon the child, the anaesthetic should not be administered until the patient is on the operating table and all pre-operative preparations made. If the operation is started immediately the required degree of anaesthesia is reached, the minimum amount will be necessary.

Another method worthy of note is to supply infiltration together with small amounts of nitrous oxide and oxygen during the operation to allay restlessness and nervous apprehension.

Yet another method is to induce sleep with a minimum dose of either evipan or pentothal sodium and continue with nitrous oxide and oxygen, gradually adding ether.

Premedication.—Unfortunately this is not permissible to any satisfactory extent as all the opium alkaloids when administered to the mother have such a depressing effect on the respiratory centre of the child.

Nembutal has been advocated and has been found to have considerable sedative effect when given in 2-gr. doses two hours and one hour before operation.

Pre- and post-operative management.—The most important advancement in pre- and post-operative management is efficient antenatal care, whereby the surgeon is warned of approaching danger. Being forewarned, a favourable time can be chosen for the operation and prolonged and futile labour is prevented.

The treatment of shock and haemorrhage by blood transfusion or intravenous infusion of glucose-saline or gum solutions before operation is undertaken and by intravenous infusions whilst it is in progress is also a useful development.

Important improvements have been made in post-operative treatment. Pain, which is always severe in the abdominal wound and which is sometimes increased by cramp-like uterine contractions, is relieved by lavish doses of morphia. Ergometrine is injected intramuscularly twice daily and when vomiting ceases may be given as a pill thrice daily for four or five days.

If, before operation, uterine haemorrhage was severe, blood transfusion by the continuous drip method is instituted or resumed. The addition of alcohol to the infusion has a restorative and sedative effect.

The patient should be nursed in the Fowler's position to promote uterine drainage, and, should peritonitis ensue, limit the infection to the pelvic region. Should signs of pyrexia arise, full doses of sulphanilamide or M&B. 693 should be prescribed.

Abdominal distension is a common complication of Cæsarean section, though usually to a less marked degree when the extra-peritoneal operation has been performed.

Paralytic ileus is a common complication also, and must be differentiated from intestinal obstruction.

A comparatively rare complication except in minor degree, but one which must be kept in mind, is acute dilatation of the stomach, a highly dangerous condition with grave prognosis unless efficiently treated.

Cæsarean section, like all surgical procedures, is dangerous, destructive and deplorable when misapplied, but when well chosen and conducted by the most up-to-date methods is one of the greatest life-saving operations, and it must be remembered that usually two lives are involved.

Some Recent Advances in Vitamin Therapy

By T. D. SPIES, M.D.
D. P. HIGHTOWER, M.D.

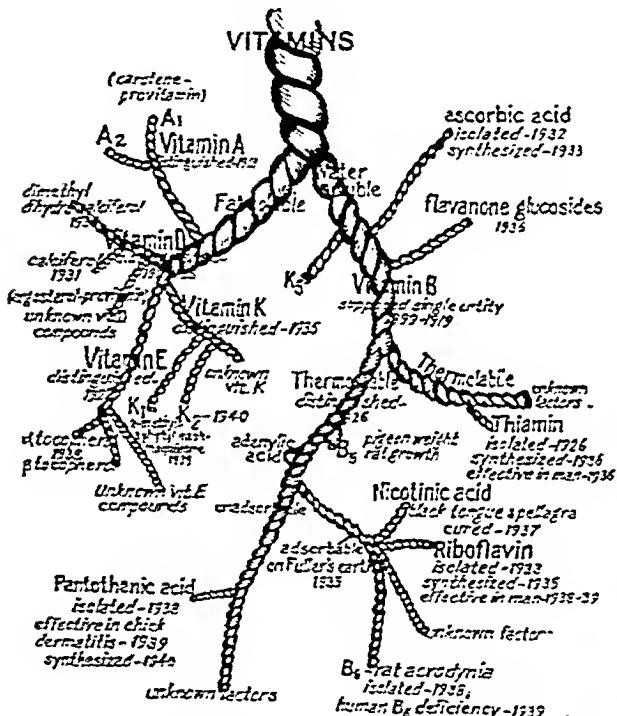

and

L. H. HUBBARD, M.D.

(From the *Journal of the American Medical Association*, Vol. CXV, 27th July, 1940, p. 292)

Long after beri-beri, rickets, scurvy and pellagra were recognized and described by physicians, the concept of

nutritional deficiency diseases arose. With the development of this concept, a new chapter in medicine came into being. Of late considerable research has been directed toward the isolation and synthesis of so-called accessory food factors, more commonly known as vitamins, and some of these substances have been found effective in the treatment of beri-beri, rickets, scurvy and pellagra. The years following the brilliant investigations which led to the isolation, synthesis and clinical trial of thiamine hydrochloride, nicotinic acid, riboflavin, vitamin E, vitamin B₁ and pantothenic acid have, however, been marked by a period of confusion. The literature with regard to these vitamins, and to the deficiencies arising from a suboptimal amount of them, is vast and often contradictory. The problem is so complex and the precise knowledge so meagre that we must accept the point of view that a rising curve of complexity is on us. The accompanying illustration shows this complexity. Accordingly, it seems wise to restrict this report to the present status of a few of the therapeutic advances made in the field of nutrition since 1936.

Diagrammatic representation of the interrelationship of the vitamins. They are schematically differentiated into the water-soluble and the fat-soluble fractions; the latter group is further separated into its thermolabile and its thermostable components. Certain of these substances have been shown to be essential to human nutrition and effective in the treatment of specific deficiency diseases. The physiological properties of many are as yet undetermined.

1936: THIAMINE HYDROCHLORIDE

The synthesis of vitamin B₁ (thiamine hydrochloride) in 1936 accelerated clinical investigation and made possible intensive study of the nature of symptomatology of beri-beri. Beri-beri, in its severe form, affects predominantly the peripheral nervous and the cardiovascular systems. It is characterized by a symmetrical peripheral neuropathy accompanied by degeneration and atrophy of the muscles supplied by the affected nerves, and by cardiovascular disturbances which include edema, cardiac dilatation, speeded circulation, high venous pressure and prolonged electrical systole. The study of many patients with beri-beri has shown that they experience a long period of ill health, characterized by prodromal symptoms, before the recognizable symptoms of the disease appear. These prodromal symptoms include loss of weight, strength and appetite,

periodic vertigo, burning sensations in various parts of the body, nervousness, numbness, loss of sensation in the extremities, and cramps and tenderness of the muscles.

Vitamin B₁ is of considerable value in the treatment of beri-beri and of the acute neuropathy associated with chronic alcoholic addiction, pellagra and pregnancy. Enough information is available to warrant the trial, under controlled conditions, of this substance for persons who have peripheral neuritis associated with dietary deficiency. Vitamin B₁ does not act as an analgesic, and it is our belief that this substance is most useful in the amelioration of the early disorders caused by a deficiency of vitamin B₁. The administration of synthetic vitamin B₁ (thiamine hydrochloride) to persons with acute beri-beri relieves the cardiovascular disturbances, induces improvement in response of the muscles innervated by affected peripheral and cranial nerves, restores the normal electrical conductivity of peripheral nerves, relieves gastrointestinal dysfunction resulting from thiamine deficiency, increases carbohydrate tolerance and decreases bisulphite binding substances in the blood. In cases of subclinical thiamine deficiency it often increases the appetite, strength and feeling of well-being and relieves the symptoms arising from early neurological lesions of beri-beri.

1937-1938: NICOTINIC ACID

The isolation of nicotinic acid amide from liver concentrates marks a milestone in our progress in the study of pellagra. Nicotinic acid amide, nicotinic acid, sodium nicotinate, the diethyl amide of nicotinic acid (nikethamide) and other related compounds have been found to relieve many of the symptoms of pellagra. Clinical pellagra is a systemic disease which affects chiefly the alimentary tract, skin and nervous system. Typical glossitis, which is characterized by swelling and reddening of the margins and tip of the tongue and which, as the disease progresses, extends to involve the entire tongue, is one of the earliest symptoms diagnostic of the disease. Stomatitis, gingivitis and pharyngitis also develop and progress in a similar way. These lesions of the mucous membranes are often infected with Vincent's organisms. Nausea, vomiting, ptomaine, diarrhoea and abdominal distension are usually advanced symptoms of the disease. The dermal lesions of pellagra may occur on any part of the body. These lesions usually are bilaterally symmetrical and are sharply demarcated from the adjacent healthy skin. At first the erythematous area somewhat resembles sunburn, but later in the course of the disease the colour changes to reddish brown, desquamation begins and the underlying skin is seen to be abnormally red and thickened. Permanent pigmentation may develop following frequent recurrences of the dermatitis. In pellagrins, severe mental disturbances, such as apprehension, confusion, disorientation, hallucinations, mania and delirium, are an indication of a very advanced stage of the disease. However, these advanced symptoms are preceded by a period during which the patient complains of loss of weight and strength, lassitude, abdominal pain, numbness, nervousness and forgetfulness. An initial nervous syndrome, characterized by hyperesthesia to all forms of sensation, increased psychomotor drive, anxiety and apprehension with a tendency toward depression, weariness and increased fatigability, headaches and sleeplessness, is typical of this prodromal period. Recognition of these early symptoms and immediate application of therapy prevents the development of classical pellagra.

The administration of adequate amounts of nicotinic acid, or compounds acting similarly, to persons with acute or relapsed pellagra will cause fading of the fiery red lesions of the mucous membranes and striking improvement in the Vincent's infection associated with it, revive the appetite and restore normal alimentary function, sometimes with a return of gastric hydrochloric acid, increase strength and feeling of well-being, and restore to normal deranged mental functions; provided they result from pellagra and are not of too great chronicity. In cases of subclinical pellagra these

synthetic chemical substances will relieve indigestion, diarrhoea, burning of the tongue and stomach, burning and itching of the skin, dizziness, forgetfulness, confusion, insomnia and the symptoms of the initial nervous syndrome. Nicotinic acid will also cause disappearance of the abnormal ether-soluble red pigments which are present in the urine of pellagrins, increase the content of coenzymes I and II in the blood and urine and increase the nicotinic acid content of the blood and urine of both normal persons and persons who have a deficiency of nicotinic acid amide.

1938-1939: RIBOFLAVIN

The importance of riboflavin in human nutrition was observed independently by Sebrell and Butler and by the Vilters and Spies. Lesions at the corners of the mouth (*cheilosis*) were first described by Sebrell and Butler as a typical manifestation of riboflavin deficiency. Erosions around the eyes and a shark skin appearance of the skin over the nose are also characteristic of a deficiency of this substance. Itching, burning and excessive dryness of the eyes, photophobia, granulation and extreme redness of the conjunctiva, particularly of the lower lids, are rather common complaints among persons suffering from riboflavin deficiency. These conjunctival manifestations are often associated with keratitis.

The administration of riboflavin is followed by disappearance of the cheilosis and 'shark skin' lesions of the nose, improvement in general vigour, increase in the sense of well-being, and relief from the ocular symptoms. In addition, it increases the efficacy of nicotinic acid in the treatment of certain pellagrins.

1939-1940: VITAMIN K AND VITAMIN B₂

Vitamin K.—Vitamin K, a fat-soluble vitamin, is essential for the maintenance of a normal concentration of prothrombin in the blood. Animal experimentation and clinical studies have shown that certain haemorrhagic tendencies are due to a low plasma prothrombin resulting from a vitamin K deficiency. Absorption of this fat-soluble vitamin is dependent on the presence of bile in the intestine rather than on the adequacy of vitamin K in the diet. Lowered prothrombin concentration may occur in conditions in which extensive intestinal lesions interfere with absorption or, more frequently, in conditions in which bile is excluded from the intestine by obstruction of the common bile duct. In such cases the administration of vitamin K will restore the normal prothrombin level. Bile salts, of course, must be given along with the orally administered vitamin in cases in which bile is not present in the intestine; otherwise the vitamin will not be absorbed. Recent work also indicates that newborn infants have a vitamin K deficiency in the first few days of life and that the administration of vitamin K will prevent and cure the haemorrhagic diathesis in at least many cases of 'haemorrhagic disease of the newborn'.

Pyridoxin (vitamin B₆).—Clinical studies to determine whether vitamin B₆ is essential to human nutrition were undertaken in 1938, soon after the artificial synthesis of this vitamin was accomplished. Spies, Bean and Ashe, in a preliminary report, described the favourable symptomatic response to vitamin B₆ by four persons who failed to recover completely when on a selected diet supplemented with thiamine hydrochloride, riboflavin and nicotinic acid. The symptoms responding favourably to vitamin B₆ included extreme nervousness, insomnia, irritability, cramping pains in the stomach, weakness, muscular rigidity, and difficulty and awkwardness in walking. More recently we have treated twenty additional patients with similar results. Vilter, Schiro and Spies reported that this vitamin, when administered in large amounts, produced a slight reticulocytosis in persons who have macrocytic anaemia associated with pellagra or pernicious anaemia in relapse. These studies, however, do not imply that vitamin B₆ is an anti-pernicious anaemia factor or the extrinsic factor of Castle. Improvement has been noted following the intravenous administration of vitamin B₆ to some patients with idiopathic epilepsy and to persons with amyotrophic lateral sclerosis. One of us (T. D. S.)

has seen three cases of myasthenia gravis which showed pronounced improvement within twenty-four to forty-eight hours after the injection of vitamin B₆.

On the basis of the dramatic and beneficial effect of vitamin B₆ in relieving muscular weakness and rigidity, an effort was made to determine whether a similar response would follow its administration to persons with Parkinson's syndrome, a severe lingering disease characterized by tremor of the extremities, weakness, delay of voluntary motion and muscular rigidity. In April last Dr. Norman Jolliffe reported the effect of vitamin B₆ in relieving the rigidities and weakness in certain cases of *paralysis agitans* (Parkinson's syndrome). More recently Spies reported before the Illinois State Medical Society the results of studies concerning the use of vitamin B₆ in eleven selected cases of parkinsonism of at least four years' duration, eight of which were arteriosclerotic and three post-encephalitic. Within a few minutes there was much improvement in the latter three. Rigidity was decreased significantly and the patients were able to walk without the usual stiffness. Two of the arteriosclerotic patients showed definite improvement, five were unchanged and one was considerably worse. Dr. Jolliffe has stated that in a study of thirty patients with *paralysis agitans* he observed 'no apparent improvement in the post-encephalitic group, little or no improvement in any group of patients hospitalized for over three years and dramatic improvement in approximately 20 per cent of the patients with nonpost-encephalitic parkinsonism who had been helpless for less than one year'. These preliminary observations indicate to the authors that rigidity in some cases seems to be decreased and that vitamin B₆ should have more careful study. It seems likely that some persons with Parkinson's syndrome may have an associated vitamin B₆ deficiency, for indeed it is the close resemblance of the rigidity and awkwardness in walking observed in patients suffering from either disease which prompted us to administer vitamin B₆ to those with Parkinson's syndrome.

Many more studies are necessary before conclusive statements can be made concerning the effect of this vitamin on persons with various diseases. It must be emphasized that a sedative effect of vitamin B₆ may be responsible, in part at least, for the rapidity with which symptoms are relieved and that the administration of this vitamin is warranted only under controlled conditions.

1940: VITAMIN E, YEAST ADENYLIC ACID AND PANTOTHENIC ACID

Vitamin E.—For several years it was believed that vitamin E was concerned specifically with reproduction. During the past decade, however, a definite relationship between an inadequate intake of vitamin E and the normality of the cross striated musculature of the body has been established. Characteristic muscular atrophy occurs in widely divergent animal species when vitamin E is withdrawn from their diets. Restoration occurs following the intramuscular injection of synthetic alpha-tocopherol (vitamin E). During the past year Wechsler and Spies and Vilter observed independently that synthetic alpha-tocopherol has a beneficial effect on occasional persons with amyotrophic lateral sclerosis. The injection of 500 mg. of alpha-tocopherol in sterile oil is effective, at least temporarily, in relieving neuro-muscular symptoms, roaring sensations in the ears, anorexia, and insomnia of selected persons with malnutrition but without clinical evidence of pellagra, beri-beri or riboflavin deficiency. We have observed striking improvement in a few of these people following the administration of vitamin E, but it is difficult to measure objectively the degree of improvement. It would seem that the patients who experience the greatest relief are those who also have some deficiency of vitamin E.

Clinical studies of the therapeutic effect of vitamin E are still somewhat in an experimental stage, and until further work is done the administration of this substance is warranted only under controlled conditions.

MARCH, 1941]

Yeast adenylic acid.—Adenylic acid is a constituent of the pyridine dinucleotides, coenzymes I and II, and since these intracellular enzymes are fundamental to physiologic processes it was felt that adenylic acid merited consideration for study in the treatment of persons with mixed deficiency diseases. Accordingly, we administered yeast adenylic acid to normal persons and to poorly nourished persons who had symptoms which were not relieved by nicotinic acid, thiamine hydrochloride, riboflavin, vitamin B₆, or vitamin A. The injection of from 3 to 20 mg., dissolved in sterile physiologic solution of sodium chloride, within fifteen seconds produced involuntary, deep, gasping inspiration, fluttering sensation in the upper part of the abdomen and a feeling of fulness in the head. All patients had transient flushing of the neck and face, and the pupils became widely dilated. These symptoms vanished within a few minutes and left no evidence of a harmful effect. Less intense symptoms of the same type followed the administration of a single dose of 200 mg. of adenylic acid by mouth. Six patients with mal-nutrition who had intense burning of the oral mucous membranes but no diagnostic evidence of pellagra were relieved following treatment with adenylic acid. The administration of this substance together with nicotinic acid to a series of pellagrins in relapse seemed to increase the effectiveness of the nicotinic acid. However, because of the severe reactions produced by the intravenous injection of yeast adenylic acid we do not recommend its administration to human beings.

Pantothenic acid.—The structure of pantothenic acid (the chick antidermatitis factor) has been determined and early in 1940 its synthesis was accomplished. Now that it is becoming available for clinical investigation, studies on its relation to the blood, urine and tissues of human beings are in progress. Since there was no information regarding the possible toxicity of pantothenic acid, we administered this substance, under controlled conditions, to a series of normal persons and found that at least 100 mg. may be injected intravenously without producing a reaction or causing a significant change in the blood pressure, pulse or respiration. Spies, Stanberry, Williams and Jukos observed that the pantothenic acid content of the blood is increased soon after injection but returns to its previous level within twenty-four hours. Stanberry, Snell and Spies have shown that the pantothenic acid content of the blood of persons having severe deficiency diseases, such as pellagra, beri-beri and riboflavin deficiency, is from 23 to 50 per cent lower than in normal persons and that with a rise in the pantothenic acid content there is a simultaneous increase in the riboflavin content of the blood. The patients with an abnormally low concentration of pantothenic acid in the blood have also had less than normal in the urine. These observations suggest that pantothenic acid is important in human nutrition.

GENERAL CLINICAL CONSIDERATIONS OF DEFICIENCY DISEASES

Factors operating to produce deficiency states.—The factors that operate to produce nutritional deficiency diseases are an inadequate intake, increased need, diminished absorption or utilization, or increased destruction or excretion of the essential nutritional substance or substances. Clinical study of deficiency disease syndromes in 3,500 persons, including the 1,500 reported in this paper, has shown that single deficiency states seldom exist. This is not surprising since the dietsaries of persons in whom these diseases most frequently occur are deficient in many essential nutrients. The resultant clinical picture is extremely complex; we frequently see evidence of pellagra, beri-beri, riboflavin deficiency, scurvy, vitamin B₆ deficiency, vitamin A deficiency and anæmia in the same person. The diagnosis of one clinical deficiency syndrome, therefore, necessitates a thorough search for others.

Factors of safety operating to correct deficiency states.—Certain factors of safety operate to protect the body and to compensate for a deficiency of these essential substances once the deficiency has set in. A wide

margin of safety exists between the beginning of a dietary deficiency disease and death from it. We have reported cases in which rest alone was followed by some improvement and, in certain instances, by healing of the lesions characteristic of a specific deficiency state. More recently we have observed a significant increase in the blood concentration of coenzymes I and II following rest in bed. When treating persons with nutritional diseases, one should therefore curtail their activities as much as possible until restoration of the affected tissue to normal is under way. Another factor of safety is the storage of these essential substances which takes place to some extent in the tissues. Also the body tends to excrete less when a deficiency exists. Nevertheless there is a limit to this self regulation and, if the deprivation of these substances continues, irreparable damage to the tissues will result.

PRINCIPLES OF THERAPY FOR DEFICIENCY DISEASES

General therapy.—The following general principles of therapy are applicable to all deficiency diseases: Each patient must be considered as an individual problem and treatment prescribed accordingly. A well balanced diet of 4,500 calories, rich in protein, minerals and vitamins, should be eaten each day. The type of food, the mode of administration and the time and frequency of feeding in the more severe cases are dependent on the patient's condition and on his ability to tolerate food. Complete reliance on dietary therapy, however, is not recommended, for the necessary protective substances are present in too small amounts to be effective in cases of well developed deficiency diseases. Furthermore, persons of the lower income group who are most frequently affected by nutritional diseases cannot afford to buy the relatively expensive foods rich in vitamins and protein. Specific therapeutic agents, then, should be given as supplements to a well balanced diet. In the very severe case hospitalization is advisable, for the combined services of a physician, nurse and dietitian are essential. The patient should be kept at complete rest in bed until convalescence is well established. If for any reason the food requirement is increased, efforts must be made to eliminate the cause. Appropriate symptomatic therapy and treatment of coexistent diseases are of course desirable. Treatment in all cases should be based on all the clinical evidence available.

Specific therapy.—Specific therapy in the form of large doses of synthetic chemical substances induces more rapid and dramatic remission of symptoms of the specific deficiency diseases, shortens convalescence in the severe case, and assures more certain recovery. The indication for therapeutic use of synthetic vitamins and concentrates of yeast and liver is very large indeed, but indiscriminate use is not consistent with the interests of the patient.

Beri-beri is treated best by giving pure crystalline vitamin B₁ (thiamine hydrochloride). The administration of 20 mg. a day in 10 mg. doses is recommended for the average case of beri-beri in the adult, and for the severe case from 50 to 100 mg. administered in divided doses. Ten mg. daily may be sufficient for the mild case. Infantile beri-beri is treated best by giving 5 mg. of thiamine hydrochloride, dissolved in sterile physiologic solution of sodium chloride, twice a day, or 10 mg. by mouth each day. The treatment of the nursing child will be greatly aided by giving the mother satisfactory anti-beri-beri treatment. Vitamin B₁ may be administered either orally or parenterally, but the latter method is preferred in the acute case because of the greater ease in giving massive doses, the greater certainty of absorption and the more rapid improvement which follows.

Nicotinie acid, nicotinic acid amide and sodium nicotinate are effective in the treatment of pellagra. These substances may be administered orally in tablets or capsules, or parenterally, dissolved in sterile physiologic solution of sodium chloride. The average adult patient will respond to the oral administration of 500 mg. daily, given in divided doses of 50 mg. each, though as much as 1,000 mg. a day may be required in the very severe cases. The parenteral dose varies

from 50 to 80 mg. daily, injected intravenously in doses of from 10 to 15 mg. Nicotinic acid amide has an advantage as a therapeutic agent in that it does not produce vasodilatation of the skin or an increase in the temperature of the skin which so frequently follows the administration of nicotinic acid and sodium nicotinate.

From 3 to 5 mg. of riboflavin, administered orally in tablet form or intravenously in sterile physiologic solution of sodium chloride, is effective for the average case of riboflavin deficiency. Since riboflavin is not very soluble in saline solution, the oral method of administration is recommended.

Very little is known concerning either the maintenance requirement or optimal dosage for vitamin K. Early work indicates the maximal prothrombin response is obtained when the crude vitamin extracted from 300 gm. of alfalfa is given orally over a period of from three to four days. Recent work has shown that the oral administration of from 1 to 5 mg. daily of 2-methyl-1, 4-naphthoquinone usually will give excellent results, though for some cases this amount will have to be increased. Since complete absorption is dependent on the presence of bile in the intestine, it is necessary, when vitamin K is administered orally, to give bile or bile salts along with it, as for example in cases of obstructive jaundice. Satisfactory results are obtained if the daily dose of the vitamin is emulsified in from 1 to 2 ounces (30 to 60 c.c.) of bile or is given with a comparable amount of animal bile salts.

The intravenous injection of 50 mg. of vitamin B₆, dissolved in sterile physiologic solution of sodium chloride, is effective in the treatment of symptoms of vitamin B₆ deficiency. Evidence indicates that vitamin B₆ will relieve, at least temporarily, certain other conditions as described in the section on vitamin B₆; but, since response is not uniformly observed in all cases, its use is not recommended until further study has been made.

Vitamin E (synthetic alpha-tocopherol) in sterile oil, injected intramuscularly in dosage of 500 mg., relieves temporarily the symptoms of weakness and pain in the legs. In some cases a second injection of 500 mg. may be required.

Because of the severe reactions produced by the intravenous administration of adenylic acid, its use is not recommended.

Stanberry, Snell and Spies have shown that the content of pantothenic acid in the blood and urine is from 23 to 50 per cent lower in persons having pellagra, beri-beri and riboflavin deficiency than in normal persons.

In the mild and moderately severe cases of mixed deficiency disease, dry powdered brewers' yeast (from 75 to 100 gm.), liver extract (from 75 to 100 gm.) or wheat germ (150 gm.) daily should be given orally as supplements to the diet. Yeast and wheat germ have an advantage over the pure chemical substances in that they contain nicotinic acid, vitamin B₆, riboflavin and vitamin B₆, as well as minerals, proteins, enzymes and salts, and probably still other as yet unknown essential factors. A strain of yeast, designated C-50, furnished by Anheuser-Busch, Inc., for experimental purposes, has been found more palatable than the other strains we have used. Many of the patients who objected to the taste of brewers' yeast will take it without complaint when it is combined up to 25 per cent with peanut butter or catsup.

SUMMARY AND CONCLUSIONS

During the past year and a half, 1,500 persons with clinically associated deficiency disease syndromes have been treated without a death. (The death rate from severe pellagra alone a few years ago was often as high as 54 per cent.) Our studies indicate that these people have a mixed rather than a single deficiency disease, and from a practical standpoint the response of these persons indicates that mixed vitamin therapy is often desirable. We recommend the administration of water-soluble vitamins together, rather than individually, and fat-soluble vitamins together, rather than individually, as having a definite usefulness in the

treatment of deficiency diseases. Even when specific therapeutic agents are administered in the treatment of deficiency diseases, persons of all ages should also be given a well-balanced high-calorie diet.

Reviews

WAR WOUNDS AND INJURIES.—Edited by E. Fletcher, M.A., M.B., M.R.C.P., and R. W. Raven, F.R.C.S. (Based on articles in the 'Post-Graduate Medical Journal'—Fellowship of Medicine.) Edward Arnold and Company, London. Pp. viii plus 262. Illustrated. Price, 14s.

THIS little book, based on articles which have appeared in the *Post-Graduate Medical Journal*, gives a résumé of the present state of knowledge of war surgery. The contributors all seem to have derived their experience from the war of 1914-1918, but they have brought it into line with the great progress that traumatic surgery has made during the post-war period. The first three chapters, on shock, gas gangrene, and tetanus, contain plenty of evidence of the advances that have been made in recent years.

The succeeding chapters deal with injuries of the various regions, the chest receiving special attention.

Lord Horder in his foreword suggests that a chapter on burns and another on sepsis would improve a second edition. Doubtless room will also be found for chapters on the early treatment of wounds and compound fractures. The book can nevertheless be recommended as it stands, and it is one that should find many eager readers in this country.

W. McN. N.

THE FOOT AND ANKLE: THEIR INJURIES, DISEASES, DEFORMITIES AND DISABILITIES.—By Philip Lewin, M.D., F.A.C.S. 1940. Henry Kimpton, London. Pp. 620, with 303 Illustrations. Price, 42s.

A LARGE part of this book consists of a review of the orthopaedic surgery of the ankle and foot. The author has gone to great pains to collect from the literature the best monographs; and much of the original text, especially of those describing operative technique, has been reproduced in full.

In an endeavour to make this as complete a work as possible the author devotes many chapters to ancillary subjects, such as the circulatory disturbances of the lower extremities, varicose veins, and rickets. There may be something to be said for the inclusion of these chapters, but it is difficult to find justification for the opening pages of the appendix at the end of the book. Here are to be found, under the title 'Footnotes and Footsteps . . . Pedigrams', about a hundred disconnected sentences of doubtful value and still more doubtful wit. Thus 'Take the arch out of your back and put it in your foot' is followed by 'Foot-care is good foot insurance'. Others of a like nature are also to be found scattered throughout the book. They do not adorn what otherwise is a valuable surgical monograph.

W. McN. N.

THE ART OF SURGERY: A TEXTBOOK FOR STUDENTS AND PRACTITIONERS.—By H. S. Souttar, D.M., M.Ch. (Oxon.), F.R.C.S. (Eng.). In two volumes. 1940. William Heinemann (Medical Books) Limited, London. Pp. x plus 779. Illustrated. Price, 25s.

THIS book was originally published in one large volume in 1929 and it met with quick success. After three editions it has now appeared in a more attractive form in two volumes presenting many new features. In spite of this the price has been reduced to 25 shillings.

The first volume, consisting of 402 pages and 29 chapters, deals with general surgery, diseases of bones

MARCH, 1941]

and joints and the nervous system. Volume 2, containing 25 chapters and 2 appendices, though somewhat smaller, deals with special subjects, including thoracic, abdominal, and genito-urinary surgery. Mr. Souttar's book is so well known that it requires no introduction. In this edition large sections of the book have been entirely rewritten and brought fully up to date. Though we are far from the turmoils of Europe, we realize that under present conditions lavishly illustrated and leisurely volumes are both outmoded and impracticable for constant use. The author's characteristic marginal drawings are numerous and are not merely effective but also conducive to economy of words.

In spite of its conciseness, this book is neither a mere 'aid' nor a synopsis. The senior student will find that it contains all that is necessary for most examinations in surgery. We agree with the author that 'it will provide the reader with a solid framework into which to fit the experience which alone can make him a surgeon'. There is such great charm in the author's diction and power of description that the book easily becomes a companion. We have no doubt that the present edition will meet with as ready a welcome as its predecessors. The printing, get-up and illustrations do great credit to the publishers.

P. N. R.

A MANUAL OF OTOLOGY, RHINOLOGY AND LARYNGOLOGY.—By Howard Charles Ballenger, M.D., F.A.C.S. 1940. Henry Kimpton, London. Pp. 302. Illustrated with 90 engravings and 4 coloured plates. Price, 18s.

This manual is intended for the student who can only spare a limited amount of time to the study of oto-laryngology. Written by the junior author of Ballenger's *Diseases of the Nose, Throat and Ear*, some of the text and most of the illustrations have been taken from the larger work. Reference to the original text reveals that considerable condensation has been made, but this has been well done, and indeed the subject-matter is often more readable. Omissions consist chiefly of operative procedures, alternative methods of treatment, and details of the rarer conditions.

Amongst the illustrations, a coloured plate depicting various diseases of the tympanic membrane is the best that we have yet seen.

This book in no way supplants the larger volume, whose merits are already well known; it should achieve popularity on its own account among those for whom it has been written.

W. McN. N.

TEXTBOOK OF MEDICINE.—By Various Authors. Edited by J. J. Conybeare, M.C., D.M. (Oxon.), F.R.C.P. Fifth Edition. 1940. E. and S. Livingstone, Edinburgh. Pp. xx plus 1131. Illustrated. Price, 24s. Postage, 8d.

LITTLE need be said about the new edition of this well-known book, for it is less than two years since the last edition appeared and was reviewed in this journal. The book is particularly designed for the student for revision of the subject of medicine, but it will equally well serve the practitioner as a reminder of the outstanding points in the pathology, diagnosis and treatment of diseases which he encounters in his daily round.

Nearly all the important cosmopolitan diseases are well, though concisely, described and the latest established methods of treatment are given. The necessity for conserving space has compelled the author of the section on tropical infections to carry compression too far, so that the diseases in this section are little more than medical dictionary descriptions. Even this does not excuse reference to distribution of the lesions of espundia as 'the converse of oriental sore' whatever that may mean, and a description of the initial lesions as occurring in the mucous membranes. The statement that 'Plasmoquine acts mainly on the sexual forms of the parasite and hence is not curative, but diminishes

the relapse rate', suggests a fundamental inappreciation of the life cycle of the malarial parasite, but is probably only a tragedy of compression: nevertheless, it might be clarified, or removed, in the next edition. Otherwise, we found little to criticize in this book which we can thoroughly recommend to the student.

THE THYROID: SURGERY, SYNDROMES AND TREATMENT.—By E. P. Sloan, M.D. 1936. Ballière, Tindall and Cox, London. Pp. ix plus 475, with 99 figures. Price, 45s.

THROUGH a series of mischances this book, which was sent to us some years ago, has not been reviewed. It is not however a book that dates, and we feel that we could like to draw our readers' attention to it, even at this late date.

No anatomical structure in the human body involves so many specialists, when it departs from the path of normal growth and function, as does the thyroid. The physician, the surgeon, and the gynaecologist, the neurologist and the psychiatrist, the cardiologist, the laryngologist, and the ophthalmologist, the biochemist and the radiologist, all play an active part in the diagnosis and treatment of the various disabilities associated with thyroid hyper-, hypo-, and dysfunction. It is therefore not a subject for a one-man monograph; the book under review bears one name on the cover, but is really the work of a team of workers, members of the staff of the Sloan clinic.

It contains a well-balanced account of the subject in all its aspects and is an invaluable reference book for anyone interested in the thyroid gland, whether from the medical, surgical, or other points of view. There is an excellent bibliography, and a large series of beautiful coloured plates illustrating stages in the operative treatment of thyroid disease.

INFANT FEEDING.—By Alan Moncrieff, M.D., F.R.C.P. 1940. Edward Arnold and Company, London. Pp. iii plus 30. Price, 1s. 6d.

The author enunciates three simple general principles of infant feeding which are too often overlooked; firstly, that each infant is an individual whose needs cannot be standardized, secondly, that the essence of successful infant feeding is common sense in the medical adviser and in the mother, and, thirdly, that a knowledge of simple mental arithmetic will solve most 'quantity' problems.

The feeding of the infant and the pre-school child is simply stated, aids to the successful establishment of breast feeding are discussed, and clear directions are given for calculating the values of the commoner supplements. Some of the subject-matter in the chapter on artificial feeding has less application for the Indian infant, but it is concise and well presented. Lactic acid milk is not dealt with.

The chapter on the feeding of premature infants might have been more comprehensive: the value of the addition of vitamins A and D to the feeds is not discussed. The difficulties and trials experienced in rearing the premature baby are not overlooked and the management of feeding is dealt with in some detail.

This is a useful and practical book of somewhat conservative outlook, at a modest price, although not the ideal textbook on the subject for Indian conditions.

L. G.

THE PERIODICITY AND CAUSE OF CANCER, LEUKÆMIA AND ALLIED TUMOURS: WITH CHAPTERS ON THEIR TREATMENT.—By J. H. Douglas Webster, M.D., F.R.C.P.E., F.F.R. 1940. Ballière, Tindall and Cox, London. Pp. xv plus 178, with 5 illustrations, 8 charts and 8 tables. Price, 12s. 6d.

THIS book is the result of an analysis of over 800 cases of neoplastic diseases to find out whether the active phases of such diseases as carcinoma, sarcoma, leukaemia, Hodgkin's disease and certain benign tumours, show any characteristic periodicity. The author states that he has discovered this to be the case in about 96 per cent of the cases studied by him.

This periodicity has shown three varieties: '(a) a standard period of thirty-three weeks (eight lunar months); or (b) half periods of approximately sixteen and a half weeks (four lunar months); or (c) multiple periods of any multiples of (a) and (b) (the intervening maxima being suppressed).' He also states that there is a seasonal periodicity about these diseases with a maximum in January to April. He finds that manifestations of periodicity are independent of treatment and that when recurrence has taken place after a long period of latency, the periodicity has been resumed as if it had never been interrupted.

The author claims sixty successful predictions of recurrences made in cases of malignant disease and considers his observations on periodicity and histological features like inclusion bodies in Paget's cells in Paget's disease, as affording circumstantial evidence in favour of the virus theory.

The author has also discussed applications of his theory to problems of diagnosis, prognosis and treatment.

The thesis is clearly presented and in great detail. It deserves to be considered a definite contribution to the study of neoplastic diseases and, when confirmed by other workers in the field, would help to bring these conditions in line with infectious diseases of known aetiology, the course of which is characterized by periodicity.

V. N.

A HANDBOOK OF TOXICOLOGY.—By B. K. Dutt. 1940. Published by Amlya Kumar Dutt, 89/C, Garpar Road, Calcutta. Pp. II plus 83. Price, Re. 1-8

THIS is a small handbook meant for students of the medical schools of India. The subject is divided into sections, such as poisoning in general, corrosive poisons, non-metallic irritant poisons, metallic irritant poisons, animal irritant poisons, cerebral poisons, spinal poison, cardiac poisons, and asphyxiants. The poisons are discussed in the form of charts and 28 of the common poisons have been thus treated. The text seems to lack careful editing, and printing mistakes are seen too often to be ascribed to the press alone. The book will be welcomed by students for a rapid revision of the subject before an examination.

S. G.

CHEMISTRY. CATECHISM SERIES. Part I:—Inorganic. Fifth Edition. Part II:—Inorganic and Organic. Fifth Edition. E. and S. Livingstone, Edinburgh. Pp. 76 in Part I, and pp. from 77 to 152 in Part II. Price 1s. 6d. and postage 3d. for each part

IN these two small volumes the whole subject is discussed in the form of questions and answers. The answers are short and in most cases explained with equations. These books are not expected to replace the standard texts on the subject but are helpful to students for a rapid revision of the important portions before an examination.

S. G.

THE RISE AND GROWTH OF THE ALEMBIC CHEMICAL WORKS: A HISTORY.—By Raj Mitra B. D. Amin, B.A., M.S.C.I. (Lond.), Managing Director. 1939. Printed and published for and on behalf of the Alembic Chemical Works Company, Limited, by N. R. Iyer at Alembic Printing Press, Baroda. Pp. 188 plus xv. Illustrated

THIS book is a record of the development of a leading firm of manufacturers of spirit and pharmaceutical products in western India. It discusses the various difficulties and problems that faced this indigenous concern ever since its inception at the beginning of this century, and how these were met and what questions still await solution. The story of its gradual development from a small alcohol distillery and chemical factory into one of India's first-grade chemical and pharmaceutical enterprises makes interesting reading. The book is an economic study of

development of an important industry in western India, and, as such, it is sure to be of considerable interest to industrialists, business men, and economists in this country.

P. C. S. G.

Abstracts from Reports

ANNUAL REPORT OF THE EXECUTIVE HEALTH OFFICER OF THE CITY OF BOMBAY FOR 1939.

THE health conditions of the city during the year were decidedly better than what they were during the previous year. This fact may be judged from the total number of deaths which was 5,479 less than that registered in 1938. It is also noteworthy that the infantile mortality recorded during the year was the lowest since the year 1873. However, it was unfortunate that soon after the rains, the city was faced with the outbreak of malaria epidemic, especially in three wards, but the timely measures taken proved effective in controlling the disease within a short interval.

The number of live births registered was 37,822, being 1,074 more than in 1938 and 6,539 more than the average of the last ten years (1929-38). The birth rate calculated on the census population of 1931 was 32.6 births per 1,000.

The total number of deaths from all causes was 30,520, being 5,479 less than in 1938, 152 less than the average for the last five years (1934-38) and 2,260 more than that for the preceding decennium (1929-38). The death rate per 1,000 of census population of 1931 was 26.3 as against 31.0 in 1938 and 23.9 the rate recorded for the decennium (1929-38).

Thus the number of births during the year was more by 7,302 than the number of deaths. This excess of births over deaths was equivalent to 6.3 per 1,000 population calculated on the census of 1931 and was recorded nine times in succession. Before 1931 there was no such excess since 1866, the year in which birth records were instituted.

There was no death from plague during the year as against 20 the average of the last ten years (1929-38).

Smallpox caused 201 deaths as against 1,862 in 1938 and 1,067 the average for the last decennium (1929-38).

There was no death from cholera as against 1 in 1938. The average for the ten years (1929-38) was 19.

Influenza was prevalent in a mild form in the city during the year and caused 58 deaths as against 80 in the preceding year and 81 the average for the last decennium (1929-38).

The deaths from diseases of the respiratory system numbered 10,772 being 2,812 less than in 1938 and 586 more than the average of the last ten years (1929-38).

Tuberculosis accounted for 2,034 deaths as against 2,078 in 1938 and 1,741 the average for the preceding decennium (1929-38).

One hundred and seventy-one deaths were due to malaria, being 68 more than in 1938 and 56 more than the average of the last decennium (1929-38). There were 761 deaths from ague and remittent fever as against 1,065 in 1938. The average number of deaths for the last ten years (1929-38) from malaria was 115 and ague and remittent fever 1,337.

The deaths among infants under one year of age numbered 10,772, being 2,812 less than in 1938 and 586 average for the last ten years (1929-38). The rate of infant deaths per 1,000 births registered was 211.7 as against 267.0 for the preceding year and 258.6 the mean for the preceding decennium (1929-38).

Compared with the decennial average (1929-38) the total number of deaths shows an increase of 2,260, the principal increase in the mortality being 586 under respiratory diseases, 552 due to old age, 446 under

MARCH, 1941]

congenital debility and diseases of early infancy, 293 under tuberculosis, 127 under dysentery, 93 under diarrhoea, 56 under malaria, 31 under diphtheria and 26 under leprosy.

On the other hand there was decrease in the deaths under smallpox by 886, under ague and remittent fever by 576, under measles by 51, under diseases of nervous system by 33, under puerperal state by 30, under influenza by 23 and enteric fever by 10.

ANNUAL REPORT OF THE HEALTH OFFICER OF THE MUNICIPALITY OF GEORGE TOWN, PENANG (STRAITS SETTLEMENTS), FOR THE YEAR 1939

The most outstanding feature of this year's work was the increase in the number of cases of typhoid fever which assumed epidemic form at the end of August and beginning of September. Eight hundred and forty-eight cases of typhoid were notified during the year but death certificates were received for 4 more who were never notified. Five hundred and seventy-five cases were treated in hospital; 106 died and 469 recovered. Two hundred and seventy-seven cases remained at home; 46 died and 231 recovered. The total number of deaths was 152; the mortality rate was the greatest between the ages of 6 and 35, 15 deaths occurring between 36 and 45 years. One hundred and fifty-two deaths attributed to the enteric group was the highest recorded and an increase of 113 compared with 1938.

Detailed investigations carried out during this epidemic showed that the spread of the disease was through some ice-cream vendors, and one ice-cream factory had several employees who gave positive Widal reaction.

Readers interested in the details of this investigation might with advantage consult the original.

Correspondence

UNOFFICIAL QUALIFICATIONS

SIR.—May I request you to make a plea through your editorial columns for raising the standard of ethics observed by Indian medical practitioners? Complaints are being received in this country that impostors are freely using the letters F.R.C.S. or M.R.C.P. after their names with impunity; some are also using the letters M.R.A.S. (member, Royal Asiatic Society, I suppose!) which is neither a medical qualification nor a recognized diploma; and others are adopting various devices to disguise their qualifications and palming them off on the unsuspecting medical and lay public as diplomas granted by the University of London or the Examining Board in England.

Both by convention and long usage the medical and lay public have come to recognize certain well-known abbreviations used in the *Medical Register* (of Great Britain) and *Lancet*, dated 31st August, 1940, as well as in the *Encyclopaedia Britannica*.

Thus, F.R.C.S., F.R.C.S.E., F.R.C.S.I. stand for Fellow of Royal College of Surgeons of England, Edinburgh, and Ireland, respectively. Similarly M.R.C.P., M.R.C.P.E., M.R.C.P.I. stand for Member, Royal College of Physicians of London, Edinburgh, and Ireland, respectively. It appears that some Indians possessing diplomas of Edinburgh or Ireland feel ashamed to own their colleges and are resorting to the practice of omitting the E or I (as the case may be) when giving their diplomas, and are thus laying themselves open to the charge of dishonesty. Should the Royal colleges in this country decide to take disciplinary action, it may have far-reaching consequences.

It also appears to me that the Secretary and Registrars of the various medical councils do not keep

themselves in touch with the examining boards in this country and consequently have been known to give wrong advice to candidates. Thus, in the Bombay Register it is stated 'the D.T.M. granted by the London School of Hygiene and Tropical Medicine...'. This school does not grant any diploma.

In recent numbers of the *Indian Medical Gazette* the names of two Indian doctors [we omit the names] are followed by the letters M.R.C.P. Neither is a member of the Royal College of Physicians of London and one does not appear to be a member of the Royal College of Physicians of Edinburgh, either.

It appears to me that on account of the exorbitant fees payable many doctors do not register their additional qualifications but contribute articles to medical journals merely to bring to the notice of brother practitioners their additional qualifications. The remedy to this state of affairs would be, (1) to reduce the fees for additional registration, or (2) to make compulsory registration of every additional qualification.

Editors of journals should also look up medical registers and verify the qualifications of contributors before publishing their articles. Articles by persons who put M.R.A.S. after their names would bring medical journalism into ridicule.

[Note.—The letter was signed by an Indian doctor at present resident in England, and was headed 'not for publication'.

Though this letter did administer a mild rebuke to us, we cannot conclude that this was the writer's sole object in sending it to us, and as he appeared to wish us to take up this cause, we feel that publishing the substance of his letter is perhaps the best way we can meet his wish.

Editors of medical journals have to take a great deal on trust; they cannot confirm all statements made by contributors. In the matter of his own qualifications, we usually accept the contributor's word, but we do very frequently, often by accident, find that they require modifying, particularly with reference to points noted by our correspondent.

The failure to add the specific 'E' or 'I' after R.C.P. or R.C.S. is probably the result of ignorance of the fact that leaving the college unspecified has any particular significance. The practice is not confined to individuals but is unfortunately common in official publications; here we must substitute the word 'carelessness' for 'ignorance'. We notice in a recently published provincial medical list, the original qualifications M.R.C.S. (Lond.) L.R.C.P. (Eng.)!

We feel that our correspondent's strictures are not entirely undeserved. We will try to do better in the future, and we hope that we shall receive better co-operation from both official and non-official contributors.—Editor, *I. M. G.*

Service Notes

APPOINTMENTS AND TRANSFERS

ON return from leave Lieutenant-Colonel J. B. Hance, C.I.E., O.B.E., Residency Surgeon, Bangalore, assumed charge of the office of the Inspector-General of Civil Hospitals, C. P. and Berar, on the forenoon of 16th December, 1940.

Lieutenant-Colonel N. S. Jatar, C.I.E., D.S.O., ceased to hold the additional charge of the office of the Inspector-General of Civil Hospitals, C. P. and Berar, with effect from 16th December, 1940.

On reversion to military department Lieutenant-Colonel W. Ross-Stewart, C.I.E., Civil Surgeon, Lahore, made over charge of his duties on the afternoon of the 10th January, 1941.

Lieutenant-Colonel A. S. Garewal, Superintendent, Central Jail, Nagpur, has been appointed to officiate as Inspector-General of Prisons, C. P. and Berar, with effect from 18th January, 1941, vice Lieutenant-Colonel N. S. Jatar, C.I.E., D.S.O., granted leave.

Major S. Annaswami made over executive charge as Superintendent of Dum Dum Central Jail to Mr. W. F. B. Beale on the afternoon of the 11th November, 1940.

Major E. A. R. Ardeshir took over charge of the office of Superintendent of Rajshahi Central Jail from Dr. Abdul Majid on the forenoon of the 17th December, 1940.

Major W. McAdam assumed charge of the duties of Civil Surgeon, Tavoy District, on the forenoon of the 10th January, 1941.

Major S. Smyth assumed charge of the office of Civil Surgeon, Lahore, on the forenoon of the 29th January, 1941.

Major G. W. Miller is appointed to officiate as Assistant Public Health Commissioner with the Government of India, vice Dr. K. C. K. E. Raja granted leave.

The undermentioned officers of the Indian Medical Service are confirmed as Agency Surgeons, with effect from the dates shown against their names:—

Major E. A. O'Connor. Dated 10th November, 1940.
Captain J. D. Grant. Dated 15th November, 1940.

The services of Captain T. C. M. M. Morrison are placed at the disposal of the Government of Bombay for employment as Surgeon to H. E. the Governor of Bombay, with effect from the 1st June, 1940.

Captain C. L. Greening, an officer of the Medical Research Department, is appointed Assistant Director, Central Research Institute, Kasauli, with effect from the 27th November, 1940, on release from military duty.

LEAVE *

Lieutenant-Colonel N. S. Jatar, C.I.E., D.S.O., Inspector-General of Prisons, C. P. and Berar, has been granted leave on average pay for 6 months, with effect from 18th January, 1941.

PROMOTIONS

Captains to be Majors

1st April, 1937

K. H. A. Gross, M.C., with seniority from 26th January, 1936.

P. J. Kelly, with seniority from 7th September, 1936.
(Previous notification in so far as it relates to these officers is hereby cancelled.)

Note.—The promotion of the following officers to their present rank of Major is antedated as shown against their names:—

P. P. Chowdry, M.C. Dated 22nd May, 1937.

P. C. Dutta. Dated 25th May, 1937.

A. K. Gupta. Dated 15th January, 1938.

S. M. Kharegat. Dated 15th January, 1939.

B. N. Hajra. Dated 1st April, 1937, with seniority from 10th May, 1936.

A. A. Pullar. Dated 12th January, 1941.

Notes (i).—The promotion of Major C. F. J. Cropper is antedated to 8th August, 1937. He qualified for accelerated promotion on 18th July, 1939.

(ii).—The promotion of the following officer to his present rank of Major is antedated as shown below:—

N. J. U. Mather. Dated 18th March, 1938.

The undermentioned officer is granted the local rank of Captain without effect on pay and gratuity whilst employed at No. 1 Coy., I. H. C., Rawalpindi, in connection with the training of emergency commissioned I.M.S. officers and emergency Sub-Assistant Surgeons:—

Lieutenant H. L. Bhatia.

Note.—The seniority of Captain P. M. Kaul in his present rank is antedated to 26th May, 1934.

RETIREMENTS

Lieutenant-Colonel J. M. Shah, M.B.E. Dated 17th January, 1941.

Lieutenant-Colonel R. H. Malone. Dated 19th January, 1941.

Lieutenant-Colonel P. Verdon. Dated 22nd February, 1941.

Notes

MYOCRISIN

A copy of the second edition of a booklet on Myocrisin has been sent to us by the makers, Pharmaceutical Specialities (May and Baker), Limited, Dagenham.

Myocrisin is sodium aurothiomalate, a compound with a gold content of 50 per cent which has been found valuable in the treatment of rheumatoid arthritis and other conditions, effecting complete cure in 50 per cent of the cases treated in the early stages. In the later stages where the condition is of long standing Myocrisin has been found to arrest the progress of the disease, increasing movement and reducing pain.

Copies of this booklet, which contain full information on the application of Myocrisin in the various conditions for which gold therapy is indicated, may be obtained by members of the medical profession on application to May and Baker (India), Limited, 11, Clive Street, Calcutta.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints gratis; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

The preparation of reprints entails rearranging the type, so that there is often a delay of a month or more, after the publication of the *Gazette*, before the reprints are ready. If reprints are not received within two months of publication of the *Gazette*, contributors should write to the Publishers.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

FRACTURE OF THE CARPAL SCAPHOID

By C. J. HASSETT

CAPTAIN, I.M.S.

Agency Surgeon, North Waziristan

FRACTURE of the carpal scaphoid is the commonest injury of the carpal bones. It is more commonly diagnosed as a sprained wrist which is a very uncommon injury. In all fractures and sprains treated in the civil and Tochi Scouts hospitals in the past year the condition occurred only once. There were 28 fractures of the carpal scaphoid in a series of 116 simple fractures treated in both hospitals in the past eight months.

The anatomy of the bone with special reference to the blood supply has been well described by Obletz and Halbstein (1938). In their paper, it is shown that in 13 per cent of the navicular bones studied by them there was no apparent blood supply proximal to the constricted midportion or waist, in 20 per cent there was a single small arterial foramen at the waist or proximal to it, and in 67 per cent there were two or more foramina proximal to the waist. Therefore, it may be seen that fractures through the constricted portion cause a severe interference of normal blood supply to the proximal fragment and in at least 13 per cent of the cases a total interception in the nutrition of this part.

These facts explain the unequal rate of union in fractures of this bone and the occurrence of avascular necrosis which will give rise, if not dealt with, to osteo-arthritis of the wrist joint. The bone may be fractured at any one of three levels : (1) the tubercle, (2) the waist, or (3) the proximal pole (*vide figure 6*). The most common injury is fracture of the waist.

The mechanism of the injury is stated to be a fall on the outstretched hand, but in our experience the fracture appears to occur with the hand outstretched and dorsiflexed or clenched in dorsiflexion in a position of radial deviation, the force giving rise to a screw movement compressing the bone between the greater and lesser multangular bones and the distal articular surface of the radius. The main strain then falls on the scaphoid causing it to fracture. There may be associated with it dislocation of the semilunar and it may complicate Colles' fracture.

As remarked previously, it is frequently overlooked, the symptoms being attributed to simple sprain of the wrist, a rare condition. Clinically there is tenderness in the anatomical 'snuff-box' which is obliterated by swelling in recent fractures. There is limitation of movement of the wrist joint, particularly dorsiflexion, and there is weakened hand grip. X-ray diagnosis requires extreme care. Radiographs should

always be taken in three planes—antero-posterior, lateral and the more important oblique view—which shows the bone in more accurate detail, that is, with the x-ray passed through the wrist at a 45° angle to the carpal plane.

Many fractures of this bone are overlooked radiologically because the fracture line is often hardly discernible. In the study of the film a magnifying glass will show evidences of pathology. If there are negative x-ray findings and the clinical signs are in favour of fracture, a repeat x-ray must be carried out one to two weeks later, when evidence of fracture will be present (*vide plate X, figures 1 and 2*). Movements of the bone causing hyperæmia and decalcification at the site of injury make the line of fracture quite clear. As a general rule, the clinical signs are more reliable than the x-ray findings.

In old or neglected fractures the fracture line develops a decalcified and cystic appearance, as may be seen from plate X, figure 3. When this cystic gap is well defined, the fracture is several months old. If the fractured surfaces are densely calcified and sclerosed the injury is generally over a year old. The treatment of recent scaphoid fractures is simple, provided accurate and continuous immobilization is properly carried out. The position of the bone, half in the proximal row and half in the distal row of the carpus, and the fact that the fracture line usually coincides with the line of the midcarpal joint, make it very liable to shearing strains. A closely-fitting unpadded plaster cast must be used, the plaster extending from the metacarpal heads to below the elbow joint. On the radial side it includes the first interosseous space and the whole of the first metacarpal. The wrist is in a position of slight dorsiflexion and ulnar adduction, i.e., the position of grip. On the palmar surface the plaster extends as far as the first palmar crease. These splints are more conveniently made from strips of lint so cut and fashioned to suit the limb. They are then soaked in plaster cream until thoroughly saturated. They are then applied and covered with one plaster bandage. The whole gives a light and durable plaster cast.

How long should recent fractures be immobilized? In our series the average period was 8 weeks and the maximum 12 weeks. The fracture is immobilized until there is accurate x-ray evidence of union. After removal of the plaster the best clinical sign is return of the hand grip to normal. Finally, the wrist must be radiographed and a lens is again used in the examination of the radiograph to determine the presence of bony trabeculae growing across the fracture line. If after the removal of the plaster clinical and x-ray signs show that the fracture is un-united, the plaster should be re-applied for a further two months and union is again tested as previously described.

Active movements of the finger should be carried out from the onset. The patient should

be encouraged to carry out his duties as far as possible. Where it is necessary to maintain immobilization for longer than normal, the wrist may be stiff after the removal of the plaster. Active movements and massage are given. If improvement does not occur the joint should be manipulated under anaesthesia followed by massage and active movements. This was necessary in one case where the wrist was immobilized for 12 weeks. He subsequently obtained a perfect result.

In neglected fractures the treatment adopted is similar to the above. This is the fracture which shows cystic spaces and decalcification along the line of fracture in the radiograph. Immobilization must be continuous and prolonged. It usually takes several months before union is secured. In cases of established non-union, that is, fractures of over one-year old and which show filling up of the cystic spaces, recalcification and sclerosis, prolonged immobilization will be unsuccessful and operative treatment is necessary.

This consists in multiple drilling. The tubercle of the scaphoid is exposed and by means of a fine drill multiple drill holes are driven across the fracture, taking care not to damage the articular cartilage. The indications for this are rare. In our series avascular necrosis occurred in two cases (*vide plate X, figure 4*). This condition occurs as a result of interference with the blood supply following the fracture. It is evidenced in the radiograph by the absence of decalcification of the proximal fragment which shows up in the x-ray to be much denser. This will be evident after the removal of the plaster when the radiograph is examined. The treatment of this condition is excision of the avascular fragment, otherwise osteo-arthritis of the wrist joint or midcarpal joint will supervene, even though the fracture is treated by prolonged immobilization and union is eventually secured.

Excision of the avascular fragment gives complete relief from pain and limitation of movement but there is some weakness of the hand grip. In the two cases where this operation was carried out, the individuals are carrying out full duties as Scout sepoy (*vide plate X, figure 5*).

The operation is performed through an incision made on the outer side of the extensor pollicis longus tendon in the anatomical snuff-box. The radial artery is displaced and the radial collateral ligament split. The bone is brought into view by ulnar adduction of the hand; the proximal necrosed fragment is identified and removed.

In cases where osteo-arthritis has supervened, i.e., in neglected fracture of many years' standing, excision of the fragment is useless. It is necessary to arthrodesis the wrist in the optimum position. This is carried out by a dorsal incision from the base of the third metacarpal to the lower end of the radius. The periosteum is incised and elevated over the lower end of the

(Continued at foot of next column)

SURGICAL COMPLICATIONS OF FILARIASIS

By P. N. RAY, B.A., M.B., F.R.C.S. (Eng.)
Calcutta

NEXT to malaria, filarial infection is probably the most widespread disease in certain parts of India, although the rate of mortality is not as high as in malaria, the amount of disability and suffering is enormous. Not being one of the fashionable diseases, it has not received in this country the amount of attention which is justly its due.

Classification of surgical complications

Before proceeding any further, it will be helpful, if we briefly refer to a practical scheme of the surgical complications.

1. Inflammatory:

- | | |
|-----------------------------|---------------------------|
| Acute: | Chronic: |
| (i) Lymphangitis. | (i) Focal spots. |
| (ii) Elephantoid fever. | (ii) Fibro-myositis. |
| (iii) Funiculitis and epi- | (iii) Epididymo-orchitis. |
| didymo-orchitis. | (iv) Hæmato-spermia. |
| (iv) Lymphadenitis. | (v) Sterility. |
| (v) Cellulitis and abscess. | |

2. Obstructive:

- | | |
|---|--|
| (i) Elephantiasis of limbs. | (v) Elephantiasis of penis and scrotum, and vulva. |
| (ii) Hydrocele, chylocele, and hæmocele. | |
| (iii) Lymphatic varix of the cord. | (vi) Chyluria. |
| (iv) Varicose lymphatic glands, inguinal lymph varix and lymphatic varix of broad ligament. | (vii) Lymph-scrotum. |

3. Allergic:

- | | |
|----------------|-----------------------|
| (i) Urticaria. | (iii) Filarial fever. |
| (ii) Pruritus. | |

(Continued from previous column)

radius and the third metacarpal. A gutter is prepared and a bone graft removed from the tibia inserted into the prepared bed. Union is secure in about four months. The wrist joint is of course stiff, but there is not the disability one would expect.

Summary

Fracture of the carpal scaphoid is a relatively common injury while sprain of the wrist is rare. With adequate treatment union is certain. Without treatment there is persistent weakness of the hand grip and all movements of the wrist are restricted. Where avascular necrosis of the proximal fragment occurs, it should be excised. In both the cases in which it was carried out a good result was obtained.

I am grateful to F./Lieut. K. R. Butler, R.A.F., for assistance with the x-ray photos and to Colonel W. C. Paton, M.C., I.M.S., inspector-general of civil hospitals, North-West Frontier Province, for permission to publish this article.

4. Carriers:

This is a useful classification, but it is important to note that generally there is considerable overlapping of different lesions.

Pathological findings

Normal habitat of the adult worm.—The filarial worm (*Wuchereria bancrofti*) in its adult or mature state is an inhabitant of the lymphatic system of man. After the larvae gain entrance into the human body they usually complete their development in the afferent lymphatics, but some of them may develop in the vicinity of their point of entrance. Filarial infestation may, therefore, be regarded as a specific affection of the lymphatic endothelium due, either to the toxin of the adult parasites, or to the damage caused by the passage or presence of the immature larvae, or by the adult parasites. This view is supported by the following facts: (1) the occurrence of primary elephantiasis in filarial subjects without lymphangitis, (2) the severe general reactions of the acute filarial attack, and (3) the immunity to filarial toxin of sufferers from malaria. Romiti (1935) has sponsored the theory of the completion of the parasitic cycle in the genital lymphatic system. According to him the different stages of infection are the result of the emigration of the adult worm from its normal habitat or its development elsewhere than in the genital tract. There are many cogent objections to this view. After an infective larva has entered the subcutaneous tissue space, it has two vehicles of dissemination (Lane, 1931). If it enters a lymphatic vessel it may come to a stop somewhere in the slow lymph current and then grow to maturity. If it enters the blood current it may make an extensive tour within the body. It is at once taken to the right heart, and thence to all parts of the body through the arterial circulation. If the capillary to which it is taken is found to be suitable, it makes its way through the wall into the surrounding tissues and finally into a lymph vessel to undergo maturity. If the larva fails to reach a suitable spot, it dies. The objection has been offered that the filarial larva is too large for the capillaries.

Changes in the lymphatic vessels and glands : Effect of living parasites on the tissues.—Evidence has gradually accumulated that adult parasites may live in numbers in the smaller lymphatics of the limbs and on the distal side of lymphatic nodes. The constant passage of microfilariae will ultimately induce considerable cellular reaction in them. Dilatation of the infested lymph vessels is an early change, but varicosity and hypertrophy are not met with until the occurrence of obstruction at a higher level. In regions of low endemicity the larvae may pass through the lymph glands of the limbs and may reach the pre-aortic group or even the cisterna chyli, and the resulting obstruction may give rise to hydrocele of the vaginal sac, lymph varix of the spermatic cord,

chylocele and chyluria. But in hyperendemic regions, the first glands (*viz.*, inguinal) through which the larvae pass are subjected to repeated traumata and are severely damaged; this results in elephantiasis of the lower limbs. In elephantiasis of the scrotum and penis, the site of obstruction is in the pelvic and iliac group of lymphatic glands.

Obstruction to lymphatic glands by parasites.—It is now clear that adult parasites may cause mechanical and inflammatory obstruction to the outward flow of lymph, as a result of which, either lymphatic varices or lymphatic oedema, or both may be set up. Owing to the existence of extensive anastomosis of lymph channels, compensatory lymphatic circulation is generally established within a short time. But before this can occur, it is necessary that there should be first an increase in the lymph pressure and dilatation of lymph vessels in the neighbourhood of the block. It has been found that about 75 per cent of adult filariae are present in dilated lymph vessels round the gland or in the capsule and the cortical sinuses of the glands. The glands containing adult parasites may show considerable enlargement owing to the formation of eosinophil granulation tissue followed by fibrosis around the parasite.

Changes round dead parasites : Chronic epididymo-orchitis.—When the parasite dies a remarkable set of reactions takes place round it, and these changes are best seen in chronic epididymo-orchitis (Ray, 1934a). The epididymis is much more enlarged than the body of the testis. If the specimens are removed before midday, numerous microfilariae are also seen within the uterine cavity of the living parent worm (plate XI, figure 1). The epididymis presents a mass of necrotic hyaline-like material in which sections of degenerating parasites can be identified (plate XI, figure 2). This area is surrounded by a zone of round-cell infiltration with some admixture of plasma and eosinophil cells and foreign-body giant cells (Ray, 1934). The presence of eosinophil cells is most marked near the vulval end of the worm. The sections through the body of the testis show scattered areas of round-cell infiltration with a varying number of plasma cells and fibroblasts in the interstitial tissues and in the neighbour-

DESCRIPTION OF PLATE XI

- Fig. 1. Showing section of an adult female filaria in a dilated lymphatic of the testicle. Note the microfilariae contained within the uterus.
- Fig. 2. Showing section of dead and degenerating adult filaria in the epididymis.
- Fig. 3. Skiagram showing calcification of dead worm in a case of elephantiasis of the leg.
- Fig. 4. Cystoscopic appearance of bladder showing masses of coagulum mostly fibrin.
- Fig. 5. Cystoscopic appearance of bladder showing the emergent clot at ureteric orifice.
- Fig. 6. Excretion urography showing radiating fibrils round the kidneys and bilateral ureteral kinks.
- Fig. 7. Excretion urography showing displacement and kink of the ureters. Note also the radiating fibrils round the kidney.

hood of the seminiferous tubules. The remains of the dead worm are shut off like a foreign body in a mass of hyaline-like material (O'Connor, 1932). Eventually the whole area may become fibrosed. Local endo-lymphangitis obliterans with dilatation and hypertrophy of the muscular coat is also generally noted. The fate of such a testis may be fibrosis, degeneration and suppuration. Calcification of the dead worms (plate XI, figure 3) is not uncommon.

Other genital lesions in filarial infection.—The pathological changes associated with lymphatic stasis, oedema and elephantiasis may now be understood. It is, however, important to note why adult filariae should be present in the spermatic cord and the epididymis in such large numbers. It appears that as a result of lymphatic blockage at a higher level, e.g., the pre-aortic group of lymphatic glands and cisterna chyli, aberrant migration of adult worms takes place into these organs. The most striking feature in chyluria is the enormous dilatation of the regional lymphatic trunks, which may be regarded as an imperfect attempt at the formation of an effective collateral circulation after obstruction to the cisterna chyli and thoracic duct. The earliest manifestation of genital filarial involvement consists of oedema in the connective tissue of the spermatic cord and the gubernaculum of the testis in the male, and the broad and ovarian ligaments in the female. The latter condition is frequently associated with dysmenorrhœa and premenstrual pain. Elephantiasis of the female external genitalia is comparatively rare. The extreme rarity of genital elephantiasis in childhood is possibly due to the absence of vascularity of the parts and their non-development before puberty (Ray, 1936).

Super-added or secondary infection.—There is little doubt that the recurring attacks of lymphangitis are primarily due to the adult parasites. The hypothesis of 'streptococcal latency' is a less satisfactory explanation of recurrent filarial lymphangitis than one based on a tuberculin-like allergy of the affected tissue resulting from numerous minor infections. Pyogenic organisms are only present as a superadded or secondary infection. The most typical instance of bacterial invasion is furnished by acute orcho-funiculitis and streptococcal septicæmia associated with filarial orchitis. The association is explained as possibly due to an upset symbiosis or to some condition of 'soil' produced by the parasites, which is suitable for the streptococcus.

Inflammatory conditions in filariasis

Acute conditions: (i) *General.*—All the acute inflammatory conditions are accompanied by high pyrexia and some focal manifestations, but these tend to become recurrent with gradual amelioration of symptoms. The lymphangitis may closely simulate erysipelas. Inflammation and suppuration are common in filarial genital

lesions because of the liability of the parts to chaffing, intertrigo, impetigo, etc.

Treatment.—In high pyrexia, Prontosil rubrum (intramuscular injections, combined if necessary with oral administration of tablets) generally gives dramatic results. Prompt local relief is obtained by elevation of the limb and application of hot fomentations (Ray *et al.*, 1938). Both short-wave diathermy and infrared therapy are found to be beneficial. A secondary streptococcal septicæmia proved in the past to be very fatal but the prognosis has greatly improved with modern chemotherapy with sulphanilamide preparations.

(ii) *Recurring lymphangitis and pyrexia.*—It is usual to classify attendant pyrexia into two groups: one with a focal exacerbation may be called *elephantoid fever* and the other due to allergy, *filarial fever*. The latter may not be allergic in origin at all, but may be due to a cryptic reaction, as, for instance, in a deeply seated or inaccessible region.

Treatment: (a) *Change of climate.*—Migration to a colder climate seldom fails. It is probable that, on account of the cold acting from the outside, a general vaso-constriction takes place, involving all the peripheral vessels and lymphatics. This leads to increased blood and lymph flow in deeper tissues and organs. As a result, the parasites are dislodged from their habitat, with marked attenuation of allergy.

(b) *Pyro-therapy.*—Induction of pyrexia as a therapeutic measure may be obtained by several methods, either separately or in combination, *viz.*, physical methods, non-specific protein and vaccine therapy and inoculation of pyrogenetic diseases.

Physical methods.—Recent methods include the use of powerful short-wave diathermy current and an electrically heated cabinet to raise the body temperature to 105°F. In suitable cases physical methods may be used in conjunction with the methods described below.

Non-specific protein and vaccine therapy.—Little need be said about milk protein preparations like 'Aolan'. Its exact mode of action is not clear, but it is presumed to be due either to the effects of induced pyrexia or to a cellular reaction—focal or general. Sulphosin, a colloidal sulphur preparation in oil, has been used in doses of 2 to 5 c.cm. for intramuscular injection with a varying amount of success. Special vaccines like T. A. B. do not act specifically (Banerjee and Basu, 1927). Dmicos vaccine, given intravenously in doses of 0.5 c.cm. increasing to 2 c.cm., is also useful for the induction of controlled pyrexia.

Induced malaria.—For this purpose benign tertian malaria is preferable to quartan malaria, or simian malaria (*Plasmodium knowlesi*). Very great care is necessary for the selection of the cases, donor and the technique of inoculation. Generally 3 c.cm. of the donor's blood is injected intravenously; there is an incubation period of

about seven days. It is necessary to allow the temperature to rise to 105°F. In the absence of any contra-indications, induced malaria appears to be an effective therapeutic measure. But further experience is necessary before it is possible to give a final opinion regarding the height and duration of pyrexia necessary for the certain destruction of the parasites.

(c) *Allergen therapy*.—A titrated preparation of filarial hydrocele fluid has been used (Goyal and Rao, 1940); it contains a certain amount of antigen, derived either from the adult parasite or microfilariae. Further work might be carried out on this subject, in comparing the antigens derived from microfilariae and adult parasites.

(d) *Drugs*.—There are no specific drugs. In many cases, 'arseno-typoid' (Banerjee) brings about a cessation of recurrent attacks of pyrexia. It has been shown by a series of electro-static experiments that certain bacteria, e.g., *Bacterium typhosum*, *B. coli*, etc., adsorb definite quantities of such elements and compounds as arsenic, arsenic sulphide, etc. The quantity of the adsorbed chemicals has been estimated gravimetrically and their toxicity assayed on animals (Banerjee and Basu, *loc. cit.*). It is probable that when the impediment to lymphatic flow is caused by a local inflammatory cellular reaction, stasis and oedema, without permanent fibrocytic changes, it may be relieved by therapeutic measures. Tryparsamide (May and Baker) has also been used.

(iii) *Acute funiculitis and epididymo-orchitis*.—These are usually accompanied by well-marked general and constitutional disturbances and formerly had a high rate of mortality. General treatment with 'Prontosil' and allied sulphanilamide drugs has proved to be very effective (Ray *et al.*, 1938). The attacks may completely subside, but terminal abscesses requiring surgical interference may form.

Chronic conditions.—Of these focal spots, fibro-myositis and chronic epididymo-orchitis require mention. In recurrent attacks of elephantoid fever or lymphangitis, maximum pain or tenderness may be referred to certain definite parts of a particular limb. On examination, small nodules or indurated areas may be located, e.g., in the calf muscles. On skia-graphy, calcified worms (plate XI, figure 3) and diffuse shadows may be seen. In cases of recurrent attacks, the focal spot is best dissected out. A localized area of fibro-myositis may be treated with diathermy and electro-therapy with the faradic current. In suitable cases of chronic epididymo-orchitis with recurrent attacks of pyrexia, epididymectomy is indicated, but in cases of massive enlargement without elephantiasis of the scrotum, orchidectomy is best performed. Sterility is usual in bilateral cases.

Obstructive conditions in filariasis

(a) *Hydrocele, chyocele, and haematocele*.—In bilateral cases, a median incision through the scrotal raphe provides a satisfactory approach.

In small and single hydroceles an inguinal incision is to be preferred. The problem of eversion of the sac or excision is decided mostly on individual preference. Unless the skin is definitely thickened, partial excision of the skin does not in the long run yield the best results. For one thing, post-operative oedema may be troublesome, and, for another, lymph serotum may follow as a complication. The explanation lies in the fact that the main lymphatics of the serotum run on either side of the median raphe. Needless injury or destruction results in further lymphatic obstruction.

(b) *In elephantiasis of the penis and scrotum*.—Excision of the elephantoid skin and, when necessary, skin grafting should be done at the same time. Many modifications are practised but Thiersch's graft is, in the majority of cases, satisfactory.

(c) *Lymph scrotum*.—This may be very distressing; the discharging fluid may be clear or chylous, and may amount to several ounces in 24 hours. No operative treatment should be undertaken until the discharge has stopped. Absolute rest in bed, elevation of the scrotum, application of lotio calaminæ, omission of fat in the diet, and mild purging are generally prescribed. The operative treatment is similar to that of scrotal elephantiasis.

(d) *Chyluria*.—It is of interest to note that chyluria is a feature of filarial lesions in some infected localities, e.g., in the United Provinces, with low filarial endemicity. It is comparatively rare in hyperendemic areas like Cochin and Puri. It has already been noted that in regions of low endemicity the larvae pass through the regional lymphatic glands in the limbs and may reach the pre-aortic group or even the cisterna chyli, which they damage, and the result is lymph varix of the cord, hydrocele, chyocele and chyluria. The essential pathological lesions consist of obstruction to the regional lymphatic systems, and even the cisterna chyli and the thoracic duct. The pathological changes in the urinary tracts are not constant. In one variety the cortex of the kidney appears swollen and soft with the pyramids standing out as clearly-defined areas; in the other variety, definite fibrotic changes are seen. Obstruction of the thoracic duct or the cisterna chyli does not invariably lead to the rupture of the varicose lymphatic trunks into the urinary tracts. In the most serious type of haemato-chyluria, there appears to be a generalized lymphangiectasis with incompetence of the lymphatic valves, allowing a direct flow of blood from the sub-clavian vein (Ray and Rao, 1939).

Some biochemical aspects of chyluria may be noted. There is a great variation in the fat and albumin content of the urine, varying from a trace to 1.1 per cent in the case of fat and from nil to 0.6 per cent in the case of the albumin. Fibrin is frequently present in the specimen collected after the midday meal. Many interesting facts are observed on the

effect of diet containing different fats, or the excretion rate of the fat in the urine. It is worthy of note that in filarial infection the blood cholesterol content is increased. The maximum noted was 0.220 and the minimum was 0.12 per cent with an average of 0.146 per cent as against the normal average of 0.116 per cent.

The mode of onset of chyluria is spontaneous, but in nearly half the cases a history of injury of some sort is forthcoming. In females, it appears to date from a parturition. In another type of case, the history is obtained that it followed a rich meal.

Investigations : Cystoscopy.—To be of value it should be performed during the flow of chyle. In about 70 per cent of cases the point of leakage is easily seen in the bladder, usually just above the ureteric bar of Mercier, but less commonly below it within the trigone. The bladder is sometimes filled with masses of coagulum, mostly fibrin (plate XI, figure 4). In about 25 per cent of cases, the chyluria is of renal origin, and a characteristic efflux or an emergent clot may be seen at the ureteric orifice (plate XI, figure 5).

Excretion urography.—With the aid of excretion urography, usually, but not in every case, a communication between the renal calices and the dilated perirenal lymphatics is clearly displayed by the presence of delicate fibrils radiating from the kidneys (plate XI, figure 6). In nearly half the cases of renal chyluria some obstruction to, or displacement of, the ureters is demonstrated (plate XI, figure 7).

Treatment.—No prophylaxis is of any avail.

(i) General treatment : This consists of complete rest in bed, elimination of fat from the diet, aperients and elevation of the foot end of the bed. This simple treatment may abort an attack if promptly carried out. There are some practitioners who prefer to give an additional amount of fat in the diet in order to compensate for its loss in chyluria.

(ii) Operative cystoscopy and ureteral diathermy : Operative cystoscopy and fulguration are successful when the leakage is slight. If clots are present, a previous bladder irrigation with 1/2,000 silver nitrate solution would be useful. Ureteral diathermy is successful in a small percentage of cases of chyluria of renal origin.

(iii) Other measures . A successful lymphatico-venous anastomosis would provide a satisfactory short-circuit for the obstruction to the cisterna chyli or the thoracic duct but has not been a surgical success.

(e) *Inguinal and spermatic lymph varices.*—The lymphatic varix of the cord is often mistaken for either a bubonocele or a hernia, and generally excised during the operation. Occasionally an intractable chylous fistula may develop. In some cases injection of a 10 per cent solution of sodium morrhuate gives excellent results. The same treatment is preferable in varicose lymphatic glands.

(f) *Elephantiasis of limbs.*—The surgical treatment of this condition has not proved to be satisfactory owing to the difficulty of establishing an efficient alternative lymphatic drainage.

Treatment : Non-operative.—In milder cases elastic bandages and supports, elevation of the limb, e.g., resting the leg upon a chair at frequent intervals, vibro-massage and faradic currents, separately or in suitable combinations, are found to be fairly satisfactory. Pyrotherapy and medicinal treatment have already been discussed, and in early cases these have proved to be of value.

Operative.—The main surgical problem is the relief of serious lymphatic obstruction.

(i) *Modified Auchincloss operation* is a plastic operation, involving removal of infected areas and blubbery tissues. In the first place, an attempt is made to remove areas that the patient has come to recognize as the starting point of painful attacks. Calcified dead worms and other 'focal spots' are also removed by means of elliptical incisions. This operation requires very delicate technique. The raising of the flap of skin demands great care and experience. The location of the diseased areas, in spite of previous skiagraphy, is not always easy.

(ii) *Gluteal-femoral plastic operations.*—This operation involves a very delicate technique into which we need not now digress. A large flap of skin is raised from the gluteal region containing a generous supply of fatty tissues and, if necessary, part of the deep or gluteal fascia. A similar flap is raised from the femoral region. The gluteal flap is brought round and planted into the femoral bed and the latter flap is grafted into the gluteal region. The object is to divert the lymphatic trunks of the lower limb into the gluteal region and develop an efficient anastomosis for the drainage of lymph via the axillary and neighbouring lymph channels.

In many cases a combination of these two operations is likely to give satisfactory results, but further experience is necessary.

(iii) *Kondoleon's operation.*—This has not proved to be successful and the relief obtained is rarely permanent.

(iv) *Lymphatico-venous anastomosis.*—Attempts have been made from time to time to make a lymphatico-venous anastomosis. Transplantation of dilated lymphatics into a neighbouring vein of a large size has been suggested, but surgically it is seldom feasible. Anastomosis between a varicose lymphatic vessel and its companion vein has not been a surgical success.

Drug prophylaxis.—No drug has yet been obtained which will satisfy the following requirements : (1) harmless to the host, (2) effective and selective parasiticide and (3) excreted into the lymphatic system. We are looking for a drug to satisfy all these points. Under medical treatment we have discussed the value of certain drugs.

'XIPHISTERNAL ACHE' OR LOW SUBSTERNAL PAIN

By RUSTOM J. VAKIL, M.B. (Lond.), M.R.C.P. (Lond.),
D.T.M. & H. (Lond.), F.R.F.P.S.G.

Honorary Assistant Physician, Sir J. J. Hospital, and
Tutor, Grant Medical College, Bombay; sometime
First Assistant to the Liverpool Heart Hospital

PAIN in the chest is quite frequently the presenting symptom in cases of heart disease. Little importance was however attached to this symptom till 1786, when Heberden presented the medical profession with a masterly description of angina pectoris. Since that time, much has been written, mainly of a controversial nature, on the aetiology, diagnosis and treatment of anginal pain. The passage of time has also served to separate pains of lesser or no significance, such as pseudo-angina or 'angina innocens' (Bourne, 1937) from true angina. In spite of the massive literature existent on the subject, at the present day, it is very probable that the subject of heart-pain has by no means been exhausted or explained.

Though atypical forms of heart-pain have figured in past medical literature, they have not received the attention they deserve; nor has any serious attempt been made to arrive at a classi-

(Continued from previous page)

Conclusion.—In a brief review, I have made an attempt to present a clear picture of the filarial problem from the surgeon's point of view, but in reality the problem cannot be subdivided into surgical and medical aspects. In many respects it resembles that of malaria and thus preventive measures are the most important (Ray, 1940).

Acknowledgments.—I wish to acknowledge my indebtedness to my numerous colleagues during many years of co-operation. I wish to offer my grateful thanks to Professor C. C. Bose and Dr. D. N. Banerjee of the Carmichael Medical College, Colonel Sir R. N. Chopra, Kt., C.I.E., I.M.S. (Retd.), and Dr. S. Sundar Rao of the School of Tropical Medicine and my colleagues and house staff in the Calcutta Medical College.

fication or clarification of this complex subject. It is possible that, with a growing knowledge of the subject, we may be able to recognize and distinguish different varieties of heart-pain by their clinical characteristics. Attempts in this direction have actually been made in recent years. Thus, German workers (Frank and Worins, 1926) have tried to differentiate true angina or angina of coronary origin from aortalgia or angina of aortic origin; such a view, if substantiated, is likely to modify to a considerable extent our present-day views on the causation of angina pectoris.

A study of the files of cardiac patients, both in private practice and in the out-patient department of the Liverpool Heart Hospital, has brought to my notice seven cases of heart-pain with features sufficiently unusual to warrant attention. While distinct in several respects from the generally recognized forms of cardiac pain (such as angina pectoris and benign cardiac pain), these cases are clinically strikingly similar, a fact which suggests the possible existence of yet another form of heart-pain. My attention was first drawn to this form of pain by two cases (cases 6 and 7 reported here) of atypical chest pain, seen within the space of a few weeks, in Liverpool. A look-out for further cases of this nature in India has been rewarded by the finding of five more cases.

In order to stress the two main characteristics of this variety of pain (*viz.*, the site and character of the pain), the designation proposed for it, as being the most suitable, is 'xiphisternal ache' or, alternatively, 'low substernal pain'. Patients, who were subject to typical attacks of angina pectoris as well as the type of pain described here, had little difficulty in distinguishing between the two types of attacks.

Case reports

Case 1.—A Parsee gentleman, aged 73, was seen in May 1939 with a few months' history of shortness of breath on exertion and attacks of giddiness; the latter symptom was usually induced by change of posture, such as bending forwards. For a few months, he had been subject to attacks of pain at the lower end of the sternum; they were usually noticed at about 4 o'clock in the afternoon and also at other times, when he was particularly tired or depressed; in his opinion, the attacks bore no relation to exercise or meals. Pain would start in the region of the xiphisternum, show a gradual increase in intensity and after a period of 'about an hour' would 'work itself off' without any treatment; alkalies were of no avail, though feeling 'depressed and shaken' the patient could carry on with his work as usual, even during the attacks.

On examination, he was thin and sparse, but highly energetic. Pulse rate was 78 per minute; pulse regular and of good volume. Blood pressure was 172/102.

The cardiac impulse was 'heaving' in character and situated in the 5th space, 4 inches from the mid-line. The first sound at the apex was prolonged and thudding in character, while the 'aortic second' was loud and ringing. No murmurs were audible.

Fluoroscopy revealed a dilated aorta (transverse diameter: 8 cm.) with a very prominent 'aortic knuckle' and moderate enlargement of the left ventricle.

After five months of treatment on a sedative mixture and 'jocapral' tablets, the patient was seen again; there was considerable relief from dyspnoea and vertigo,

while attacks of pain no longer occurred. His blood pressure, at the time, was 160/92.

Case 2.—A Parsee gentleman, aged 63, was seen early in 1939 with a history of several years of 'heart trouble'. For years he had been the subject of leucoderma. In 1927, he had an operation, in England, for pain, and paraesthesia and weakness of the lower extremities; a bony tumour was removed from the fourth lumbar vertebra with subsequent disappearance of symptoms. In 1933 he developed severe pain in the praecordium with dyspnoea and collapse, later diagnosed as 'coronary thrombosis'. Since that time he had experienced dyspnoea on effort, headaches, palpitations and throbbing in the neck and chest. He had also been subject to attacks of pain in the region of the xiphisternum; they would last for five to fifteen minutes with no tendency to radiate in any direction or cause constriction; the attacks would arise spontaneously with little or no relation to effort or emotion; the pains, which were infrequent, were of moderate intensity and did not incapacitate the patient in any way. The xiphisternum would feel sore for some time after the attacks.

On examination, the patient was well-nourished and of a highly nervous disposition. The tendon reflexes were unduly brisk except in the right leg.

Pulse rate was 82 per minute; pulse of good volume. Blood pressure 182/95. There was a trace of albumin in the urine.

The cardiac impulse, which was heaving in character, was in the line of the nipple. The second sound in the aortic area was accentuated.

Fluoroscopy revealed an 'unfolded aortic arch' with moderate hypertrophy of the left ventricle.

He has been on sedatives and theominal tablets for some time now with considerable benefit to the symptoms; his blood pressure keeps at about 170 systolic and 90 diastolic.

Case 3.—A Parsee lady, aged 53, a hypertensive for years, had an attack of coronary thrombosis about five years ago; during that attack, there was intense pain behind the middle third of the sternum; the pain lasted for about thirty-six hours; electrocardiograms taken soon after the attack showed coronary occlusion of the Q T type. Since that time she has been subject to typical anginal attacks, usually after exertion; the pain, during these attacks, usually starts behind the middle third of the sternum, radiates to the left shoulder and is relieved by rest and nitrates; it lasts for a couple of minutes or so and is associated with a feeling of tightness in the chest.

For the last few months, the patient has noticed a different kind of pain, limited to the region of the xiphisternum, with a tendency to recur at intervals of a few weeks, especially when she is 'feeling run down' or depressed. It lasts for one to two hours, irrespective of treatment, and is followed by tenderness of the xiphisternum to pressure for as long as twelve hours after the attack; the pain, which has no tendency to radiate in any direction, is not accompanied by any feelings of constriction or choking; depression, crying and other hysterical manifestations occur during the attacks; giddiness, faintness and vasomotor reactions have not been observed. The systolic pressure, which usually keeps at about 170 mm. Hg. in her case, rises to 200 or 210 mm. Hg. during the attacks.

On examination, the cardiac impulse is weak; the apex beat is in the 5th space, 4 inches from the mid-line. The first heart sound is feeble while the second is accentuated, especially at the base. There is an inconstant systolic murmur at the apex.

Crepitations are audible at both lung bases. The liver and spleen are not palpable or tender. There is no oedema of ankles or venous engorgement.

She is at present on deriphyllin (Homburg) and serpina tablets.

Case 4.—A Parsee lady, aged 60, has had moderate hypertension for years, the systolic pressure ranging from 160 to 180 and the diastolic from 90 to 100 mm.

Hg. For the last three years, she has had recurrent attacks of subacute cholecystitis with severe pains of a colicky nature. The gall-bladder attacks usually respond to injections of hexamine or cylotropin and anti-spasmodic medicaments. After each attack, the patient remains depressed and anxious for several days afterwards, in constant fear of further attacks. On three distinct occasions, during convalescence after cholecystitis, she has had pain in the lower third of the sternum, lasting for one to two hours; the pain is in the mid-line, has no relation or resemblance to gall-bladder pain and comes on even at rest; it feels 'like a lump' behind the xiphisternum, does not radiate and fails to respond to alkalies, charcoal and anti-spasmodics. During the last attack, the pulse rate was found to be 92 per minute and the blood pressure 196/102. For some hours after the attack, the xiphisternum remains tender to touch.

On examination, she is fat, has a sallow complexion and is usually depressed. The pulse rate usually keeps at 72 to 78 per minute.

The apex beat is in the 5th space, 3½ inches from the mid-line. The heart sounds are normal except for the aortic second, which is slightly accentuated. There is a soft systolic murmur in the pulmonary area. The gall-bladder area is tender to deep palpation.

Case 5.—A Hindu male, aged 55, was seen in hospital with a three months' history of breathlessness on exertion, insomnia and cough with expectoration. The symptoms started soon after an 'attack of fever'. For some time he had been subject to attacks of substernal pain. Some of these attacks of pain were of the nature of 'aortalgia', starting behind the upper half of the sternum, radiating to the left shoulder alone or to both shoulders, lasting for fifteen to twenty minutes and accompanied by zones of hyperesthesia in the left axilla and inter-scapular region at the back.

He also had attacks of pain in the region of the xiphisternum lasting for about two hours, with no tendency to radiation or to cause constriction, and associated with xiphisternal tenderness. During the attacks, he had a feeling of 'something trying to come out of the chest'; he could move about during the pain, though he preferred to 'lie back and rest'.

On examination, he was thin, intelligent and obviously worried about his condition. There was some oedema at the ankles, congestion of the neck-veins was obvious and the liver-edge was palpable and tender. The pulse rate was 85 per minute; blood pressure was 210/140. The apex beat was behind the 6th rib, 4½ inches from the mid-line and heaving in character. There was a systolic murmur in the mitral area, not conducted to the axilla.

The reflexes were brisk; his urine contained albumin.

He improved on rest, reassurance and sedatives. When last seen, his blood pressure was 180/130 and he was free from pain.

Case 6.—A married woman, aged 45, was seen in 1937 at Liverpool. She gave a four months' history of breathlessness on exertion, palpitation, attacks of giddiness and excessive fatigue.

She had always been of a nervous disposition, had 'goitre' at the age of puberty and a 'nervous breakdown' in 1927. She came of a neurotic stock.

On examination, she was a well-nourished woman of sallow complexion. She had brisk reflexes and a fine tremor in the fingers of both hands. There was some puffiness around the ankles; the liver and spleen were not palpable.

Pulse rate was 74 per minute; blood pressure was 212/132.

Urine contained albumin but no casts; fundi normal.

Arterial pulsation visible on right side of neck (Rowntree's sign).

The heart was slightly enlarged to the left; a soft systolic murmur was audible all over the praecordium.

She volunteered the information that she had been having attacks of pain 'in the bone above the pit of

the stomach'; it was more of the nature of an ache; it would come on, at intervals of a few days or weeks, usually soon after the midday meal; it would gradually increase in intensity and after lasting for about an hour or so, disappear spontaneously. During one of her attacks, the pulse rate was found to be 78 per minute, and the blood pressure 240/135; the xiphisternum was tender to pressure; a week later, her pressure was 208/130.

Case 7.—An English plumber, aged 53, was seen in Liverpool, in 1937, with a year's history of increasing breathlessness, weakness, loss of weight, swelling of both ankles and attacks of pain in the chest.

His father and one uncle had died of 'heart disease'.

He was perfectly fit till 1933, when he had an attack of 'excruciating pain' in the middle of his chest, lasting for a couple of days; it had come on in the middle of the night. He was kept in bed for a couple of weeks after the pain.

Late in 1936, he lost his son during an epidemic of influenza. During the early months of 1937, he had several attacks of pain, of moderate intensity, in the region of the xiphisternum. The pain would usually come on when mounting stairs or climbing uphill, with no tendency to radiate in any direction; during the attacks, he would get 'frightfully worked up' and worry about trivialities, though able to move about; he could get some relief from rest in bed but not from alkalies (soda-mint tablets) or charcoal.

On examination, the neck-veins were engorged and the ankles puffy. The abdomen was fatty; liver and spleen not palpable.

There was moderate enlargement of the heart, the impulse being in the 5th space, 4½ inches from the mid-line.

The resting pulse rate was 84 and the rhythm regular.

Blood pressure was 176/100. The knee- and ankle-jerks were brisk. The first heart sound was reduplicated and the second loud and ringing in character.

Fluoroscopy showed a moderately enlarged heart, of circular shape. The electrocardiogram showed 'right bundle-branch block'. While his electrocardiogram was being taken he experienced an attack of xiphisternal pain; this was relieved to some extent by a trinitrin tablet; the blood pressure rose to 201/106 during the attack. He was free from pain within twenty minutes or so and walked home.

Clinical features

Clinical features, common to all the cases in this small series, and probably representative of this variety of heart pain, are:—

- (1) Site of pain : Pain is substernal; it is situated low down, usually in the region of the xiphisternum.
- (2) Character of pain : It is usually described by the patient as 'an ache', 'like a lump in the chest' or 'like something trying to come out of the chest'.
- (3) Intensity : The pain is usually 'bearable' or of moderate intensity, seldom attaining the 'incapacitating nature' of true angina pectoris.
- (4) Radiation : Unlike angina pectoris, there is no tendency for this type of pain to radiate in any direction.
- (5) Duration : Duration of attacks is extremely variable, though not in the same patient; they last for anything from five minutes to two hours or more.

- (6) Associated phenomena : Emotional outbursts, worrying, depression and crying are frequently observed during the attacks. The patient, instead of being prostrated or immobile, often moves about during the pain. Feelings of constriction and weight, so common in angina pectoris, do not occur. There is no 'angor animi' or 'feeling of impending death'. Vasomotor reactions have not been observed.
- (7) Area of tenderness : Pressure on the xiphisternum evokes pain or discomfort during the attack; such xiphisternal tenderness may persist for several hours after each attack.
- (8) Exciting causes : Some attacks arise spontaneously, even at rest; the majority of attacks, however, are brought on by worry, depression, emotional outbursts or physical exertion. Worry appears to be the commonest predisposing factor in cases of xiphisternal pain.
- (9) Remedial measures : There is no relief obtained from the use of alkaline and carminative draughts; the action of nitrites appears to be slow in these cases. As a rule, the attacks subside spontaneously without any treatment.

Definition

'Xiphisternal ache' or 'low substernal pain' may be defined as an ache or pain in the region of the xiphisternum, of inconstant duration and moderate intensity, with no tendency to radiation, not associated with feelings of constriction or 'impending dissolution', induced as a rule by emotion or exertion and followed in most instances by tenderness at the site of pain.

The sexes appear to be about equally affected. Judging from the cases reported here, the condition appears to favour middle age.

The condition appears to be much more common in private than in hospital practice; it appears to go for the higher strata of society.

Differential diagnosis

Angina pectoris.—Xiphisternal ache differs from the angina pectoris of Heberden in several respects : (1) It is limited to the lower third of the sternum or to the region of the xiphisternum. (2) There is complete lack of radiation of pain. (3) The sense of constriction or compression of angina, frequently described as 'vice-like', is absent. (4) There is no 'angor animi' or 'sense of impending dissolution'. (5) Emotional reactions are frequently observed. (6) It results from emotion and mental efforts rather than from physical exertion. (7) It tends to last longer than angina pectoris. (8) It does not cause prostration or immobility of the patient. (9) Response to nitrite therapy is not immediate. (10) Tenderness (to pressure) of the xiphisternum is a common sequel.

Coronary thrombosis or occlusion.—Though 'xiphisternal ache' may persist for as long as two hours, it never displays the excruciating pain, dyspnoea, pallor, shock or hypotension of coronary occlusion; the fever, leucocytosis and characteristic alterations in the electrocardiogram of coronary occlusion are also absent.

Attacks of 'xiphisternal ache' do not conform to the clinical picture furnished by Levy and Bruenn (1936) of 'acute coronary insufficiency', a syndrome considered intermediate between angina pectoris and coronary thrombosis.

Benign cardiac pain.—The tendency at the present day is towards discarding the word 'pseudo-angina' for more suitable terms like 'angina innocens' (Bourne, 1935) and 'benign cardiac pain' (Bramwell). Excellent descriptions of the benign varieties of heart-pain have recently been furnished by British cardiologists. 'Xiphisternal ache' is distinguished from these forms of pain by (1) the co-existence of cardiac enlargement, usually secondary to high blood pressure, (2) the site of pain, which is substernal and never apical or infra-mammary, and (3) the absence of prostration and vasomotor phenomena.

Congestion of liver.—The co-existence of cardiac enlargement in cases of 'xiphisternal ache' may suggest a diagnosis of hepatalgia due to acute passive engorgement of the liver; in the latter case, however, pain and tenderness are not limited to the region of the xiphisternum, but involve the right upper quadrant of the abdomen and back; also the liver is enlarged and palpable in such cases; pain due to liver engorgement is usually protracted and responds to cardiac remedies and decongestives.

Gastric flatulence.—Unlike 'xiphisternal ache', pain occasioned by the accumulation of gas in the stomach is usually situated below the level of the xiphisternum, is more diffuse in character, has a tendency to shift, tends to last longer, has no relation to exercise, is associated with belching or eructations and responds to alkaline and carminative medicaments.

Xiphisternal tenderness.—No confusion should arise between the condition described here as 'xiphisternal ache' and the quite distinct condition of 'xiphisternal tenderness', the latter appears as a physical sign in conditions, as widely separated and distinct as disorders of the blood (leukæmias), hepatitis, liver congestion, gastritis and local diseases of bone. It may be noted, however, that attacks of 'xiphisternal ache' may be followed by tenderness of the xiphisternum to pressure, for a variable period of time.

Discussion and conclusions

Certain features about 'xiphisternal ache' justify its inclusion into the category of anxiety state or neurosis. The mental make-up of the affected individuals is characteristic; they are all 'hypersensitive', have brisk reflexes, are unduly sensitive to Libman's pain test (Libman,

1934) (*i.e.*, pain on pressure over the styloid process of the temporal bone), are liable to emotional outbursts and are constantly worrying and anxious about their condition. In case 4, attacks of 'xiphisternal ache' were precipitated by the fear of biliary colic; in case 2, attacks became particularly frequent when the patient began to suspect 'a tumour in the brain'; in case 7, the first attack of pain occurred soon after the death of the patient's son.

The importance of psychological factors and mental influences in angina pectoris has been stressed of late by Bourne (1937), Bourne *et al.* (1937), Roberts (1931) and others. There is no doubt that the sensitivity of the nervous system has a big part to play in determining the character of the anginal attack. In 'hyposensitive individuals', for example, angina is said to take unusual or bizarre forms (Libman, 1934; White, 1937). Would it not be possible, therefore, for the opposite condition of a 'hypersensitive nervous system', such as exists in the group of cases reported here, to modify or alter the character of an anginal attack? Also, would it not be possible for such a state to render subminimal or weak stimuli, which are normally incapable of arousing heart-pain, more liable to attain the thresholds of pain and thereby facilitate the production of anginal pain?

Besides a hypersensitive nervous system, other factors appear to be concerned in the causation of 'xiphisternal ache'. High blood pressure appears to be a constant feature of such cases; the seven cases reported here are all subjects of hypertension; while in four of the cases there is a superadded history of coronary occlusion in the past, the others reveal nothing suggestive of a coronary aetiology. Hypertension cannot be held solely responsible for 'xiphisternal ache', in view of the fact that the great majority of cases of high blood pressure do not at any time experience this form of pain. The frequent association of cardiac neurosis with organic heart disease is too well known to need reiteration.

Records of blood pressure taken during and between attacks of pain have invariably shown transitory rises of systolic pressure, of about 20 to 40 mm. Hg., during the attacks; such rises of pressure are usually associated with subjective feelings of discomfort, occipital headache, throbbing in the neck and chest and vertigo.

The above facts suggest the likelihood of several factors being concerned in the pathogenesis of 'xiphisternal ache', *viz.*, (1) a hypersensitive nervous system or psychological factors, (2) organic heart disease, usually secondary to high blood pressure, (3) transitory rises of systolic blood pressure (? hypertensive crises). Whether all these factors are actually concerned in bringing about 'low substernal pain', is difficult to say in the present state of our knowledge, which can only be described as fragmentary.

If it is not too presumptuous on my part to conjecture an opinion, I may make the

tentative suggestion that the type of pain described here as 'xiphisternal ache' be regarded as a *forme fruste* or anomalous form of angina pectoris. In spite of the many points of dissimilarity, clinically demonstrable, between true angina and 'xiphisternal ache', the anginal character of the latter is suggested by the co-existence of organic heart disease and by the hypertensive crisis which occurs during the attacks. Clinical differences between the two types of pain (angina pectoris and 'xiphisternal ache') are perhaps due to the hypersensitive state of the nervous system in the latter.

A perusal of the literature reveals frequent references to mild and atypical forms of angina pectoris, some of which display striking similarity to the type of pain described here as 'xiphisternal ache'. Thus, Osler (1916) refers to the so-called 'mildest form' of angina as 'a feeling of substernal tension, uneasiness, or distress, rising at times to positive pain, usually associated with emotion, but soon passing off' and 'without accurate localization or radiation'. In his short treatise on medicine, Basu (1929) stresses the importance of distinguishing true angina from 'the substernal sensation of light oppression felt by some people with high blood pressure, on hastening to catch a train or bus'. In his opinion, such mild forms of pain (so-called angina mitis of Allbutt) are not at all uncommon in India.

Summary

(1) Attention is drawn to an atypical form of heart-pain; the designation 'xiphisternal ache' (or alternatively 'low substernal pain') is suggested for it, as being the most suitable.

(2) Seven cases of hypertensive disease of the heart exhibiting this form of pain are described.

(3) The clinical characteristics are enumerated and the differential diagnosis discussed.

(4) Factors which are possibly concerned in the genesis of 'xiphisternal ache' are considered. The condition is regarded as a *forme fruste* or anomalous form of angina pectoris liable to arise in individuals of a 'hypersensitive type'.

A REPORT ON THE USE OF CADMIUM SULPHIDE IN THE TREATMENT OF PULMONARY TUBERCULOSIS AT THE JADABPUR TUBERCULOSIS HOSPITAL

By K. S. RAY, M.A., B.Sc., M.B., Ch.B. (Edin.)

Superintendent

N. N. SEN, M.B. (Cal.), T.D.B. (Wales)

Assistant Superintendent

and

H. N. DAS GUPTA, B.Sc., M.B. (Cal.)

Assistant R. M. O.

Jadabpur Tuberculosis Hospital

For the last few years, gold salts have been used extensively for the treatment of pulmonary tuberculosis, but their high price has placed them well beyond the means of the average patient. It is a common experience to find poor patients exhausting their resources on a few tentative doses of gold preparation, much too small to produce any tangible result, and then giving up treatment in despair. Our attention was drawn to the possibility of using cadmium in place of gold by an article of Heaf in the *British Journal of Tuberculosis* (1937). Cadmium being a cheaper metal would certainly bring relief to the poor patient of this country, if in action it were anywhere near the gold preparations. If this was true in 1937, it is far more so in 1941, when, due to war conditions, not only has the price of gold salts gone up, but the question of their availability is becoming increasingly serious. We are relating our experience with cadmium after having tried it in 100 cases, and we feel sure it would be of interest to those who have to deal with large numbers of tuberculosis patients.

Our work is spread over a period of about three years extending from October 1937 to September 1940. One hundred cases of pulmonary tuberculosis were treated with injections of cadmium sulphide during this period. Of these, 20 cases having received less than ten injections are excluded from this report. Forty-six of the remaining 80 cases were treated with cadmium sulphide alone and the rest received cadmium sulphide in combination with phrenic evulsion or artificial pneumothorax.

As early as 1913, Lumiere and Chevrotier tested the inhibiting influence of various metallic salts on the growth of tubercle bacilli. They found that chlorides of cadmium and mercury retarded its growth even in a dilution of 1 : 4,000.

Lund treated 38 cases of pulmonary tuberculosis with cadmium diuretin. He claims that 24 of these cases lost tubercle bacilli from their sputum. There were some pleural reactions simulating dry pleurisy.

Walburn (Wells and Long, 1932) assessed the value of 42 different metals in the treatment of tuberculosis produced in rabbits. His report is that only cadmium and manganese when given in minute doses produce some curative effect.

Heaf (1937) treated a series of cases of pulmonary tuberculosis with sulphide or glycine of cadmium. His opinion is that the compounds are absolutely harmless and the beneficial results obtained by their use are quite worthy of comparison with results of gold therapy.

Robertson (1939) treated 16 cases on the same lines as Heaf with sulphide of cadmium. He reports that radiologically there was no improvement in any of these cases except one who had doubtful lesion at the apex, but he made no mention of the clinical aspect of these cases.

However, the promising reports of all these workers except Robertson justify an earnest attempt to assess the proper value of cadmium sulphide in the treatment of pulmonary tuberculosis.

Selection of cases

Our cases were selected at random and not according to any definite plan. At first, only rather advanced cases were available for this new treatment. Later on, as some of these cases improved clinically without showing evidence of any reaction, a few cases with brighter prospects agreed to be treated with this new metal instead of gold. According to the anatomical extent of the lesions the cases might be classified as follows :—

Group I.	Cases with small apical lesion without breakdown in one or both lungs ..	5 cases
Group II.	Cases without breakdown whose total lung area affected does not exceed that of a lobe ..	6 "
Group III.	Cases with not less than two lung lobes affected without breakdown and all cases with breakdown	69 ..
	TOTAL ..	80 cases

Pharmacology and dose

Very little is known about the pharmacology of this metal. The few animal experiments that are on record show that in poisoning doses it produces loss of appetite, vomiting and albuminuria. It is probably excreted through the kidneys and salivary glands. All previous workers are absolutely silent about its mode of action in tuberculosis.

We followed strictly the technique of Walbum who stressed the efficacy of very small doses. A one-per-cent emulsion of cadmium sulphide in sterile olive oil containing 0.25 per cent of phenol was used for injection. The usual dose was 1 c.cm. given intramuscularly once a week. In some of the afebrile cases with good general condition the same dose was given twice a week. The average number of injections given per patient was 31.8, which corresponds to 0.318 grammes of the sulphide. The maximum number of injections given to a patient was 161, equivalent to 1.61 grammes of the sulphide.

We are greatly indebted to Dr. K. L. Shaha of Oriental Chemical Works, Ltd., for preparing the emulsion for us and supplying it in 1 c.cm. ampoules. He used freshly precipitated and

dried cadmium sulphide to prepare the emulsion. It is now available in the market under the trade name of theocardium 'A' oleosum.

Preliminaries and contra-indications

The urine of the patient was carefully examined for presence of any albumin and sugar before starting a course of these injections as well as after each subsequent injection of cadmium. The following symptoms were considered to be contra-indications for starting these injections. If any of these symptoms did appear during a course, the injections were temporarily withheld and restarted after at least a couple of weeks from the subsidence of these symptoms.

- (a) Presence of albumin or sugar in the urine.
- (b) Persistent presence of a temperature above 101°F.
- (c) Presence of diarrhoea, colitis or vomiting.
- (d) Presence of haemoptysis even in the mildest form.

Reactions and complications

Practically no definite reaction was observed in most of these cases throughout their course of injections. A few cases did have occasional coloured sputum for which, knowing the advanced condition of the patients, it will be an injustice to blame the injections. Some of the cases treated were under observation for more than a year, yet they did not show evidence of any cumulative action of the metal.

Results of treatment

It is very difficult to estimate the proper value of any special treatment when we know that fresh air, good food, rest and graduated exercise are playing their parts as well. It becomes still more misleading when combined with some form of surgical treatment. The only way to neutralize these factors is to compare results with some recognized methods of treatment carried under similar conditions. In the subsequent tables results obtained with cadmium therapy alone is compared with those obtained with cadmium plus collapse therapy. The average of these two results is again compared with similar averages of solganal 'B' (Ray et al., 1933) and sanocrysin treatment (Ray et al., 1932) reported from this hospital.

A. Effect on physical signs (tables I and II).

One word of explanation is necessary about table I. Of the 11 early cases in the whole series, 10 were treated with cadmium alone and one case with cadmium and collapse, which fact has somewhat vitiated the figures. If these early cases are excluded the percentages of cases benefited are—

with cadmium alone 30.5 per cent instead of 45.6 per cent,

with cadmium and collapse 42.4 per cent instead of 44.0 per cent, which correctly represents the true state of affairs.

TABLE I
Effect on physical signs

Treatment received	Total cases	Totally arrested	Considerably improved	No improvement
Cadmium alone	46	7 or 15.2%	14 or 30.4%	25 or 54.4%
Cadmium and collapse	34	6 or 17.6%	9 or 26.4%	19 or 56.0%
TOTAL	80	13 or 16.2%	23 or 28.7%	44 or 55.1%

TABLE II
Effect on physical signs

Average of	Total cases	Totally arrested	Considerably improved	No improvement
Cadmium treatment	80	13 or 16.2%	23 or 28.7%	44 or 55.1%
Solganal 'B' treatment	42	8 or 19.0%	12 or 28.5%	22 or 52.5%
Sanocrysins treatment	32	6 or 18.7%	9 or 28.1%	17 or 53.2%

B. Effect on tubercle bacilli in the sputum.

TABLE III

Particulars of treatment	Cases with tubercle bacilli in sputum	Rendered tubercle bacilli negative
Cadmium alone ..	30	8 or 26.6%
Cadmium and collapse ..	29	14 or 48.3%
Average of cadmium ..	59	22 or 37.3%
Average of solganal ..	36	12 or 33.3%
Average of sanocrysins ..	32	13 or 40.6%

C. Effect on fever.

TABLE IV

Particulars of treatment	Febrile cases	Rendered afebrile
Cadmium alone ..	33	8 or 24.2%
Cadmium and collapse ..	27	14 or 51.8%
Average of cadmium ..	60	22 or 36.6%
Average of solganal ..	36	10 or 27.7%
Average of sanocrysins ..	28	9 or 32.1%

D. Effect on skiagram.

It is impossible to give a comprehensive idea of the changes from the very limited number of skiagrams at our disposal. During the earlier part of the treatment the lesions tend to become more dense and harder. These densities are very slowly replaced by fibrous deposits, taking several months over the process. There was no complete clearing of the lesions in any of the cases.

From the tables it will be evident that the result of treatment of combined cadmium and collapse therapy is somewhat superior to that of cadmium therapy alone. When comparing the average results of cadmium, solganal and sanocrysins, similarity of the figures is very striking.

This fact will lead one to believe that if there is any curative effect of solganal and sanocrysins in pulmonary tuberculosis, it must be possessed and to an equal extent by cadmium sulphide as well.

Advantages and disadvantages

The points in favour of cadmium therapy are that it is very cheap and, being an insoluble compound, its absorption can never be sufficiently rapid to produce any toxic symptom. The only drawback is the enormous time required to inject a quantity of the compound sufficient for producing curative changes in the lesions. This may, however, be got over by increasing the amount and increasing the percentage of cadmium from 1 to 2 per cent without much difficulty.

Conclusions

From the foregoing paragraphs we are justified in drawing the following conclusions :—

- (1) When used alone, cadmium gives almost equally good results like those of solganal and sanocrysins in the treatment of pulmonary tuberculosis.
- (2) It is a valuable adjunct to collapse therapy.
- (3) Its cheapness is an additional advantage.
- (4) The course of treatment is very long. This may be shortened by increasing the dosage.

Our thanks are due to all colleagues in the hospital for collaboration and assistance.

REDUCTION OF BENEDICT'S SOLUTION BY URINE DURING A COURSE OF SULPHATHIAZOLE THERAPY

By RICHARD E. STRAIN, M.C.P.&S., M.D., M.C.C.
Miraj Medical Centre, Miraj, India

SULPHATHIAZOLE is a new member of the sulphonamide group which promises soon to be available to the general medical profession; therefore, the occurrence of a substance in the urine which reduced Benedict's solution is of interest, as to date no mention of this reaction has appeared in the literature on the subject which is available. The following is a history of a patient with *Staphylococcus aureus* and *Streptococcus haemolyticus* septicæmia in whom copper was constantly reduced during sulphathiazole therapy although the blood sugar was 73 mg.

M. R. R., a seven-year-old boy, was admitted into the Miraj Medical Centre on 12th September, 1940, complaining of severe pain in the right hip of eight days' duration. While being chased by a dog, he fell heavily on the right hip. The dog bit him superficially, but the boy arose and was able to walk without difficulty for 24 hours. He then began to complain of pain in the right hip and to limp. Fever, swelling of the hip and chills followed in rapid succession. Distension of the abdomen and red urine was noted three days after onset. A local doctor was consulted, compresses applied to the hip and medicine given to reduce fever. After two days of such treatment, hospital admission was sought. The patient was said to have had malaria three months previously.

The temperature on admission—101.6; pulse—128; respiration—26; blood pressure—115/75. The patient was thin, toxic appearing with dry skin, and an infected abrasion of the scalp 2 inches in diameter was present. Moderate distension of the abdomen was present. A hot tense swelling involving the upper thigh and right hip joint extended anterior to the iliac crest. No definite fluctuation could be made out. The leg was markedly abducted and flexed on the thigh. All motion was painful but, with care, passive motion was not limited. The superficial dog bites had healed without scarring or infection.

It was felt the boy had acute osteomyelitis involving the right hip and pelvis associated with abscess formation. Immediate x-ray examination did not disclose any abnormality of hip or pelvis. In the laboratory, the white blood count was 16,000 with 75 per cent polymorphonuclears; 24 per cent lymphocytes; 1 per cent monocytes. Haemoglobin was 70 per cent (Sahli). The patient could not void on admission and catheterization was not done. 500 c.c.m. of 5 per cent glucose was given intravenously immediately: the urine, collected after this was given, was dark yellow, acid, specific gravity 1005, albumin present, 0.2 per cent sugar, leucocytes present in a fair number, but no red blood cells or casts. Fluids were given freely, the urine became negative for sugar; the following day under general anaesthesia an incision was made over and slightly above the greater trochanter; the muscles split and about four ounces of thick yellow pus evacuated, the last portion of the pus being watery. Smears were positive for staphylococcus and streptococcus. The joint was not opened. Drainage was provided.

Post-operatively, the temperature fell to normal, but reached a peak of 102° on the third day. Smears for malaria were negative, but quinine sulphate, 20 grains daily, was started. Blood culture taken on the sixth day after operation was reported positive for staphylococcus and streptococcus. Sulphanilamide, 4 grammes daily, was given for eight days without relief at which time the colony count was 8 per c.c.m., 7 *Staphylococcus*

aureus and 1 *Streptococcus haemolyticus*. The haemoglobin fell to 45 per cent (Sahli), and the white blood cells to 3,400; 30 per cent of these were 'stab' or young forms; 35 per cent were segmented polymorphonuclears. The urine consistently contained albumin and white blood cells with no red blood cells or casts, and no further sugar was noted after the first specimen collected shortly after intravenous glucose was given.

After the 15th blood matching, the boy's mother was requested to appear and did so after some delay on the 13th day after operation; her blood was matched and 300 c.c.m. of blood was given. Swelling was noted the day prior to transfusion in the perineal region and incised, with the liberation of a small amount of thin watery pus. The temperature was lower for three days.

Sulphathiazole was secured and started immediately after discontinuing sulphanilamide; 2 grammes given as the initial dose followed by 1 gramme every four hours for the next seven days. The morning after sulphathiazole, the urine contained 1 per cent sugar although no glucose had been given for three days. During sulphathiazole, the urine consistently contained from 0.5 per cent to 1.0 per cent sugar with the fasting blood sugar of 73 mg. No glucose was administered until a day after sulphathiazole was stopped, when the urine, for the first time since starting sulphathiazole, was negative for sugar. It remained negative for sugar until discharge.

A blood culture, taken on the last day of sulphathiazole therapy, was negative as was another taken eight days later. Seven days of sulphathiazole therapy had sterilized the blood stream which remained sterile. The pus from the wound showed marked diminution in the number of organisms—so much so that this was noted spontaneously by the laboratory examiner. An x-ray film taken at this time showed marked and widespread destruction of the right ileum extending into the acetabulum. On the first day of sulphathiazole therapy, a metastatic abscess had appeared over the left humerus, but healed promptly with incision. The smear showed many staphylococcus and streptococcus. Although laboratory improvement was marked, the temperature continued to reach 102° daily. The patient did not appear so toxic and seemed much better for four or five days. Then, swelling of the feet and eyes developed; the serum proteins were 5 mg.; blood urea was 40 mg.; blood plasma from the 'blood bank' was given; at this time I became sick and during my absence, discharge was requested and granted without my knowledge. Red blood cells had appeared in the urine, for the first time in the hospital, 12 days after sulphathiazole was stopped. Albumin was also increased in quantity; no casts were observed.

This case presents several points of interest. The first of these is the fact that sulphathiazole effected sterilization of the blood stream where sulphanilamide had failed to do so. One would have anticipated that sulphanilamide probably would not affect the staphylococcus, but one would anticipate the streptococcus would be cleared. Sulphathiazole, in this instance, exerted a more powerful effect against the streptococcus than sulphanilamide had appeared able to do.

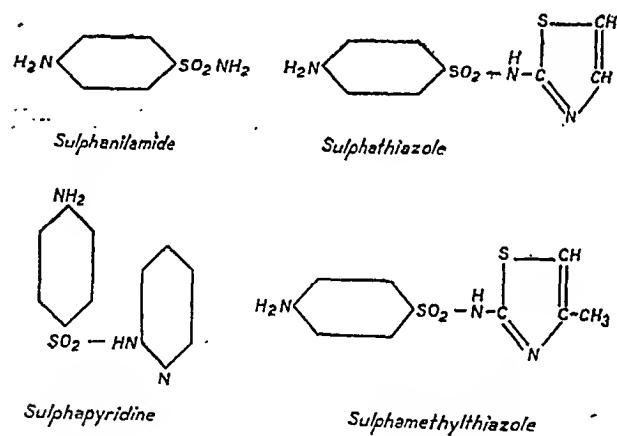

In the second instance, sulphathiazole effected sterilization against staphylococcus where all other measures had failed.

In the third instance, sulphathiazole seemed to either lower the kidney threshold for sugar in this instance, as a copper-reducing substance was consistently present in the urine with a blood sugar of 73 mg., or some copper-reducing substance was excreted by the kidneys when sulphathiazole was administered as this disappeared promptly with the stoppage of the drug and did not re-appear. This effect was not

observed with sulphanilamide. It is regrettable a sugar tolerance test was not done prior to the discharge so that a more accurate idea of the mechanism involved might have been obtained.

In the fourth instance, sulphathiazole either did not prevent the formation of a haemorrhagic nephritis or had no effect of a beneficial nature upon nephritis which was probably present on admission. Neither did it appear to aggravate any condition that may have been present as its action on the kidney is thought to be purely mechanical, as far as causing haematuria is concerned, and red blood cells first appeared in the urine 12 days after stoppage of the drug which is rapidly eliminated.

The various properties of sulphathiazole are fast becoming a matter of increasing importance, and now that the drug is available for general distribution, a knowledge of its place in the group of sulphonamides is essential. A few well-founded facts can be enumerated from the available literature. The following structural formulae show the relationship between the four drugs of this group :—

A major part of the facts now known about this new drug are listed below :—

Sulphathiazole's acute toxicity is definitely less than sulphapyridine or sulphamethylthiazole (Long, 1940).

Sulphathiazole is more readily absorbed from the gastro-intestinal tract than is sulphapyridine and is more rapidly excreted (Long, *loc. cit.*).

Much larger amounts of sulphathiazole are excreted in the urine; after injection it can be recovered quantitatively. It has been found very efficacious against infections of the urinary tract caused by *Staphylococcus aureus* and *Streptococcus faecalis* where sulphanilamide is valueless. It will not overcome infections secondary to some definite pathological obstruction, however, as this is too much to expect of any drug (Pool and Cook, 1940).

Against gonorrhœal urethritis, sulphathiazole has demonstrated a rapid beneficial effect (Stirling, 1940; Lloyd and Erskine, 1940).

In furunculosis, sulphamethylthiazole has proved of definite beneficial value (Gruelle and Mason, 1940).

Experimentally, in pneumococci, meningococci, haemolytic streptococci, lymphogranuloma venereum, and plague, sulphathiazole has been found to be of beneficial value. Clinically, relapses in pneumonia have been more frequent with sulphathiazole than with sulphapyridine. This is explained on the basis of more rapid excretion (McKee *et al.*, 1939).

Reactions : These are fairly common with sulphathiazole, but do not have the severity of the other drugs of the group.

Skin. Rashes of three types have been noted—a maculo-papular, urticarial and erythema nodosum. Rashes developed in 13 per cent of 76 cases (Haviland and Long, 1940).

Eye. Conjunctival and scleral injection restricted to the bulbar conjunctiva and sclerae occurred in 9 per cent of 76 cases (Haviland and Long, *loc. cit.*).

Gastro-intestinal. Nausea occurred in 20 per cent of cases (Pool and Cook, *loc. cit.*) but was not associated with vomiting. No acidosis is produced by sulphathiazole, so administration of soda is not necessary.

Genito-urinary. Haematuria associated with dumb-bell, rosette and chestnut-burr-shaped crystals in the urine has been reported repeatedly (Long, *loc. cit.*; Arnett, 1940). Catheterization of the ureters and lavage with warm water may be necessary in cases of urinary suppression.

At the present time there is no evidence to believe that any kidney damage, other than mechanical, is exerted by the drug.

'Drug fever'. Drug fever associated with marked vertigo, headache, nausea and palpitation is reported (Pool and Cook, *loc. cit.*).

Hæmopoietic system. Sulphathiazole is said to contain the same inherent tendency of sulphonamide groups to depress the hæmopoietic system and daily red blood cell counts and white cell counts are indicated. In this case, although the leucocytes were only 3,400 at the start of sulphathiazole and large doses were given to a small boy, no depression of the leucocytes was noted.

Dosage. Two initial doses of 2 to 3 grammes each have been recommended followed by 1 gramme every 4 hours for an average-sized adult. This dosage has proved adequate in *Staphylococcus septicæmia*, urinary tract infections caused by *Staphylococcus aureus*, *Streptococcus faecalis*, or gonorrhœa, but has been followed by relapses in pneumococci infections. The drug usually exerts a beneficial influence early—within 48 hours or not at all. Reactions usually occur after 4 to 5 days' administration, although they may occur after the initial dose of the drug (Pool and Cook, *loc. cit.*).

Summary.—A case of staphylococcus and streptococcus septicæmia is presented in which a copper-reducing substance was excreted by the kidney constantly during sulphathiazole therapy, although the blood sugar was 73 mg. This cleared promptly with stoppage of the drug.

URINARY EXCRETION OF NICOTINIC ACID IN PELLAGRINS

By B. NAGANNA, M.Sc.

K. V. GIRI, D.Sc., A.I.I.Sc.*

and

P. VENKATESAM, M.B., B.S.

(From the Department of Biochemistry, Andhra Medical College, Vizagapatam)

WHEN the identification of pellagra-preventive factor with nicotinic acid, and the therapeutic value of nicotinic acid and its amide in the treatment of pellagra became established, it was desirable to devise methods for their quantitative determination in urine, in order to provide useful information in clinical investigations and for assessing the level of nutrition with respect to nicotinic acid, similar to those already in use for vitamin C and vitamin B₁.

Various methods have been suggested for the quantitative determination of nicotinic acid. All these methods are based on the reaction in which the pyridine nucleus of the nicotinic acid is broken down by cyanogen bromide and an aromatic amine to give a compound which is coloured yellow. The intensity of the colour, which is a measure of the nicotinic acid content, is determined colorimetrically. Various amine reagents have been suggested for the development of the colour and it is found that p-aminoacetophenone, which has been recently introduced by Harris and Raymond (1939), possesses many advantages over the reagents (aniline, metol, etc.), suggested by other workers (aniline

by Swaminathan, 1938; Kringstad and Naess, 1939; Pearson, 1939; Ritsert, 1939; metol by Bandier and Hald, 1939; naphthylamine by Euler *et al.*, 1938). The intensity of the colour produced with this reagent is very high and it is 3 to 5 times as sensitive as aniline and metol. The colour is quite stable and the reaction is found to be very specific for nicotinic acid. By employing this reagent Harris and Raymond (*loc. cit.*) worked out a method for the determination of nicotinic acid content in urine. The Pulfrich photometer was used for the estimation, and the nicotinic acid content was calculated by extrapolation of the line drawn from the photometric readings. As the photometer is not easily available in ordinary biochemical laboratories, we have modified the photometric part to adapt the method to ordinary colorimetry. The principle of the method is, however, the same as that described by Harris and Raymond. As long as the urine is coloured yellow to brown after hydrolysis with sodium hydroxide, this method works well. In those cases where the urine exhibits an intense red colour after hydrolysis, which is very rare, it is rather difficult to obtain accurate values.

We describe below the principle involved in the method and its application to the determination of the urinary excretion of nicotinic acid in normal persons and pellagrins. The response to test doses, which indicate the degree of 'saturation' of pellagrins with respect to nicotinic acid, has also been investigated.

Method

The reagents, CNBr solution (saturated bromine water decolorized by 10 per cent KCN) and p-aminoacetophenone (1 gr. dissolved in 2.8 c.cm. 10 per cent HCl and made up to 10 c.cm. with water) were prepared as described by Harris and Raymond.

Twenty-five c.cm. of the urine were measured out into a conical flask, 5 c.cm. of 20 per cent sodium hydroxide solution were added and kept in boiling water-bath for about 30 minutes, in order to convert the nicotinamide into nicotinic acid. The solution was then neutralized with concentrated HCl after the addition of 2 c.cm. of 4 per cent NaHCO₃ to stabilize the end-point. The solution was finally adjusted to pH 6.0 (bromothymol blue as indicator) by the addition of dilute HCl or NaOH as the case may be, and diluted to 50 c.cm.

Four graduated glass-stoppered cylinders (20 c.cm. capacity) are taken, the first one serves as blank, the second one, the unknown and the third and fourth are controls to which known amounts of nicotinic acid are added. These cylinders will be designated as x, A, B and C, respectively. To B and C are added 0.2 c.cm. and 0.4 c.cm. of standard nicotinic acid solution (1 c.cm. = 100 μ) respectively. Ten c.cm. of the dilute urine solution are pipetted into each of the four cylinders and kept in the hot water-bath at 80°C. for about 10 minutes. Then 2 c.cm. of CNBr reagent is added only to the last three, i.e., A, B and C, but not to x (to which 2 c.cm. of water is added instead), shaken well, and after 4 minutes the cylinders are kept in cold water. After 4 minutes' cooling

(Continued from previous page)

This must be a rather rare reaction for the drug and confined to a group of susceptible persons as no reports of similar cases have been published in the wide use of closely related drugs.

I wish to acknowledge the kind and instantaneous co-operation of Lieut.-Colonel S. S. Sokhey, Director, Haffkine Institute, Bombay, who furnished the sulphathiazole used.

0.2 c.cm. of the amine reagent is added to all the four cylinders and after mixing well, they are kept in a dark place, covered with black paper in order to avoid exposure to light. After 15 minutes 0.4 c.cm. of 10 per cent HCl solution is added, and the colours compared in a colorimeter after 15 minutes keeping in a dark place.

Calculation.—Harris and Raymond calculated the nicotinic acid content of the experimental solution by drawing a graph, taking the photometric readings as measured with the Pulfrich photometer with S 47 filter, as ordinates and the corresponding known amounts of nicotinic acid added as abscissæ. The straight line which is thus obtained is produced backwards to cut the axis and the distance between the origin and the point at which it cuts the axis represents the amount of nicotinic acid in the solution.

The principle of this method has been applied by using the ordinary colorimeter to measure the intensity of the colour. The method we have adopted is fully described below.

The blank solution x is taken as standard, against which the intensity of the colours of the other three samples was determined. The ratios, 20/R (where R is the colorimetric reading obtained for A, B and C, when the reading for x is 20), between the intensities of the colours of x on the one hand and A, B and C on the other were determined, and is subtracted from each of the values thus obtained. A graph is constructed taking these values as ordinates and

the total amount of nicotinic acid can be easily calculated.

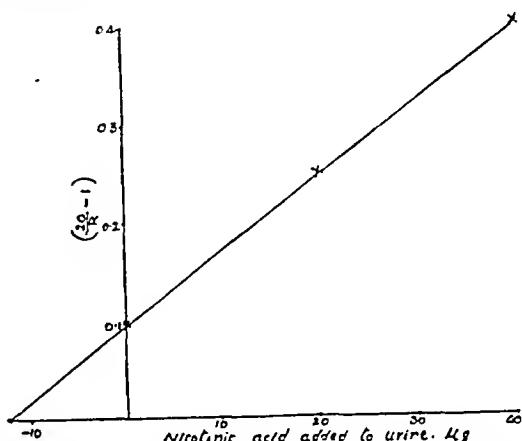

Fig. 1.—Graph showing the relation between the colorimetric values and the corresponding known amounts of nicotinic acid added to the urine.

$$\text{Nicotinic acid content} = 12.5 \text{ mg.}$$

Urinary excretion of nicotinic acid in normal adults.—The method described above was applied to the determination of the amount of nicotinic acid excreted in 24-hour urine by normal persons consuming an adequate diet and we found the figures to vary from 4.8 to 6.1 mg. In the following table are given the range of values obtained for the urinary excretion of nicotinic acid in normal adults as determined by various workers in different laboratories.

TABLE I

	x blank used as standard and kept at 20 mm. representing the colour of the urine	COLORIMETRIC READINGS		(20/R-1)
		R	Ratio between the standard and the experimental solution (20/R)	
A. Unknown	20	18.3	1.1	0.1
B. Unknown + 20 γ nicotinic acid	20	16.0	1.25	0.25
C. Unknown + 40 γ nicotinic acid	20	14.4	1.4	0.4

the corresponding amounts of nicotinic acid added (0, 20, and 40 γ, respectively) as abscissæ. The line so obtained by joining the points is produced backwards till it meets the abscissæ somewhere at a point away from the origin. The distance between the origin and the point at which the line meets the abscissæ is a measure of the nicotinic acid content of the urine. To make it more clear the principle of the method is illustrated by the following example:—

In figure 1 the values (20/R-1) are plotted against the amounts of nicotinic acid (0, 20 and 40 γ) added to the urine. On producing the line backwards it cuts the abscissæ at a point which corresponds to 12.5 γ nicotinic acid present in 10 c.cm. of the urine solution. From this value

TABLE II
Urinary excretion of nicotinic acid in normal adults

Author	Place	Nicotinic acid excreted in 24 hours, mg.
Harris and Raymond (1939).	Cambridge	3.0 to 5.0
Rosenblum and Jolliffe (1940).	New York	3.4 to 10.2
Swaminathan (1939)	India (Coonoor)	3.15 to 6.77
Present authors ..	India (Vizagapatam)	4.8 to 6.1

From the above table it is clear that irrespective of nationality the daily excretion of nicotinic acid by normal adults may be taken to lie between 3.0 to 10 mg., the lowest value being 3.0 mg. If the nicotinic acid content of urine is below 3.0 mg. the person may be considered to be deficient in this vitamin.

Urinary excretion of nicotinic acid in pellagrins.—We studied the excretion of nicotinic acid in three pellagrins of whom two happened to be wife and husband. The wife showed more advanced pellagrous symptoms than the husband. We studied this case in detail and investigated the response to test doses of nicotinic acid. In the following table are shown the nicotinic acid content of the urine of the three pellagrins as soon as they were admitted to the hospital.

TABLE III
Urinary excretion of nicotinic acid in pellagrins

Sex	Age	Nicotinic acid excreted in 24-hour urine, mg.
1 Female ..	18	0.0
2 Male ..	32 (husband of patient no. 1).	0.0
3 Male ..	20	1.8

The results show that a negligible amount of nicotinic acid is excreted in the urine of the pellagrins.

Next we investigated the response to test doses of nicotinic acid in one case. This pellagrin is a female aged about 18 years. When admitted to the hospital she presented typical pellagrous symptoms with dermatitis on the dorsum of both the hands and two small patches of skin lesions on the lateral part of the arm. Gastric analysis showed that she suffered from achylia.

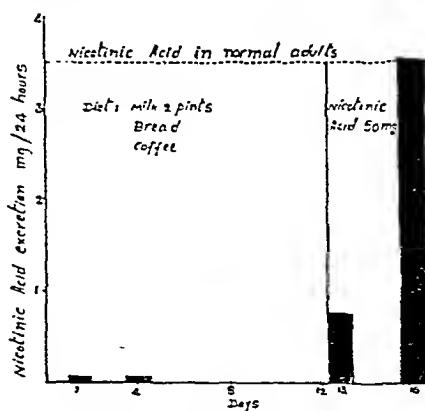

Fig. 2.—Excretion of nicotinic acid in a pellagrin.

The variation in the levels of nicotinic acid excretion of the patient with diet and treatment

with nicotinic acid is shown in figure 2. It can be seen from the figure that the nicotinic acid content of the urine, when the patient was admitted to the hospital, was practically nil, and later increased slightly on hospital diet consisting of bread and milk. The excretion of nicotinic acid attained the normal value only after the administration of nicotinic acid (50 mg. daily). As soon as the normal value had been reached, the external symptom, dermatitis, completely disappeared. Thus, it would appear that the determination of the nicotinic acid content of urine may afford a useful guide in the treatment and clinical investigations of pellagrins. It affords a valuable and probably an earlier diagnosis of pellagra.

Summary

Harris and Raymond's method for the estimation of nicotinic acid content of urine has been modified to adapt the method to ordinary colorimetry. The method was applied to the determination of the urinary excretion of nicotinic acid plus nicotinamide expressed as nicotinic acid. The nicotinic acid content of the urine of typical pellagrins was found to be negligible; it increases somewhat when the patient is put on hospital diet consisting of milk and bread. Administration of 50 mg. of nicotinic acid daily (intramuscularly) raised the nicotinic acid content of urine to normal value, when all the typical symptoms of pellagra disappeared.

Acknowledgments

The authors wish to acknowledge with thanks facilities granted by Major J. F. Shepherd, principal, and Professor V. K. Narayananamnen for carrying out the above investigations in the biochemical laboratories of the Andhra Medical College, Vizagapatam. The authors also wish to acknowledge valuable assistance received from Dr. C. K. Prasada Rao in supplying material and other useful information regarding the treatment of the cases reported in this paper, and also to Dr. K. N. Pisharotti, second physician, and to the superintendent of the hospital.

THE USE OF CASSIA FISTULA IN THE TREATMENT OF BLACK-WATER FEVER*

By K. VENKATACHALAM

and

A. N. RATNAGIRISWARAN
(Medical College, Madras)

BLACK-WATER fever is an acute febrile disease of unknown causation, characterized by rapidity of the destruction of the red blood cells and the subsequent onset of haemoglobinuria and jaundice.

This disease occurs extensively in tropical Africa and in certain regions of India. It has been reported to occur also in many other parts of the tropics. In the Madras Presidency, it is endemic in the Agency Tracts of Ganjam, Vizagapatam, and East Godavari districts, and occurs sporadically in the Kollegal taluk of the Coimbatore district, Gudalur taluk of the Nilgiris district, and the Wynnaad taluk of the Malabar district. In these areas it has been known to occur mostly during the winter months, the onset being sudden, the course rapid, and the mortality high.

The aetiology of the fever is still uncertain and no specific remedy is yet available for the treatment of the disease. However, it is claimed in some of the affected areas that the liquid extract of *Cassia beareana* gives satisfactory results in relieving the symptoms of this disease. This extract is prepared from the root-bark of *Cassia beareana*, a tree native to tropical East Africa. The tree owes its present name to its discoverer O'Sullivan Beare, an English doctor. This species does not grow either in India or Ceylon. An investigation was therefore undertaken to find out if any of the indigenous species of the cassia family could be utilized as a substitute for *Cassia beareana* in the preparation of a therapeutically active extract. In the course of the investigation an extract prepared from the root-bark of *Cassia fistula* was found to give encouraging results.

Cassia fistula, belonging to the natural order Leguminosae, is a native of tropical Asia and grows abundantly all over India and Ceylon up to an altitude of 3,000 feet above sea level. It occurs in the form of a small spreading tree not more than 20 to 30 feet in height. Its long pendulous racemes of bright yellow flowers and fresh green leaves appear together in April. Sometimes a second flowering occurs in autumn also. Its long pendulous sausage-like pods, 1 to 1½ feet in length, ripen in the cold season. It is known as Konrai or Sharakkonrai in Tamil, Rela Chettu in Telugu, Konnai in Malayalam, Kakakayi in Kanarese, Soudhali in Bengali, and Amaltas or Kirvali in Hindi.

Chemical examination

One kilogramme of the powdered bark was extracted with different solvents in succession

and the extracts so obtained were submitted to a chemical examination.

(1) Petroleum ether extract.—The red oily residue contained a small amount of a fat, a phytosterol and a red colouring matter.

(2) Ether extract.—The dark greenish-brown mass, which had a bitter and astringent taste, was found to contain an acidic substance which gave reactions resembling those of gallic acid but which could not be identified for lack of sufficient material. Oxyanthraquinone substances which appeared to consist of a mixture of emodin and chrysophanic acid from which no crystalline substance could, however, be separated were also present, in addition to a large amount of a dark-red substance of the nature of a phlobaphene and catechol tannins.

(3) Absolute alcoholic extract.—The dark-red mass consisted largely of phlobaphenes, tannins, reducing sugars and a small amount of oxyanthraquinone bodies. The latter seemed to contain substances of the same nature as were obtained in the ether extract.

(4) Ash.—The bark left on incineration 11.4 per cent of ash which was analysed and found to contain iron 1.42 per cent calculated as Fe_2O_3 , calcium 1.69 per cent, carbonate, and silica.

An estimation for tannin by the A. O. A. C. (1935) method showed that the bark contained about 14.86 per cent of tannin.

Method of extraction

The powdered root-bark was exhausted by percolation with cold 90 per cent alcohol and the percolate was concentrated under reduced pressure so that one millilitre of the final extract corresponded to one gramme of the bark. When this extract was sent out for trial, complaints were received from a few places that its administration produced severe nausea and vomiting. It was also noticed in the laboratory that, on keeping, a brown deposit had formed after about a month's storage. Examination revealed that it was due to the slow precipitation of resino-tannols and their oxidation products which might have caused the undesirable symptoms reported. After a series of experiments it was found that the use of 60 per cent alcohol for the extraction excluded a considerable proportion of these undesirable constituents without in any way affecting the therapeutic efficacy of the extract. Hence 60 per cent alcohol was employed as the menstruum in later extractions which were carried out as described below:—

One thousand grammes of the powder was exhausted with cold 60 per cent alcohol by the reserved percolate process. Eight hundred c.cm. of the percolate was obtained thereby to which was then added 100 c.cm. of glycerine and the final volume was made up to one litre with 60 per cent alcohol. The extract was filtered after keeping for a fortnight. Clinical trials with the extract thus made gave satisfactory results without producing the undesirable

* Read before the Indian Science Congress held at Madras during January 1940.

symptoms reported in a few cases of the earlier series.

This extract was distributed to the district medical officers, East Godavari, Vizagapatam and Ganjam districts, the civil surgeon, Vizagapatam Agency, Vizianagram, and the Vizagapatam Agency surgeon, Koraput, for trials in cases diagnosed as black-water fever. The drug was tried in a series of 33 cases admitted in the different hospitals and dispensaries in the jurisdiction of the above officers. From the case-sheets received from the medical officers who treated these cases, the results obtained may be summarized as below :—

(a) Number of cases in which the drug was not retained due to vomiting	4
(b) Number of cases that ended fatally	1
(c) Number of patients who were cured	26
(d) Number of cases in which treatment with the drug could not be pursued for want of sufficient stock of the drug at the time the patients were admitted in the different hospitals	2
TOTAL	33

The first four cases represent those that were treated with the drug prepared by the earlier method of extraction using 90 per cent alcohol as the menstruum. A full course of treatment could not be given in two cases, as the medical officers who attended on these patients ran short of the drug. So, only 27 cases were actually treated with the extract prepared by the modified method of extraction described above. Of these 27 cases, one ended fatally, the death having been due probably to the debility and anaemia produced on account of a prolonged fever. The remaining 26 patients recovered. In these cases haemoglobinuria completely disappeared invariably in 3 to 4 days after the administration of a total quantity of the extract ranging from 12 to 16 fluid drachms, though in a few cases the urine had cleared the next day, and in one isolated case it took 6 days for the urine to become normal. The extract has been given, generally mixed with alkaline mixtures, in $\frac{1}{2}$ to 1 drachm doses repeated every four hours, and in some cases even every hour or two according to the severity of the symptoms and the condition of the patient. No untoward effects were noticed in any of these cases. The number of cases apparently cured being 26 out of 27, the percentage of apparent cures worked out at 96.3 per cent. The medical officers who used the drug are of the general opinion that the results obtained were very satisfactory and that the drug can safely be used as a substitute for extractum cassia beareana liquidum.

In view of these results it is considered that this extract of *Cassia fistula* should be employed in the treatment of black-water fever on a more extensive scale.

Our thanks are due to the medical officers in the Ganjam, Vizagapatam and East Godavari

A SEARCH FOR LATENT SYLVATIC PLAGUE IN CALCUTTA

By C. L. PASRICH
MAJOR, I.M.S.

Professor of Bacteriology and Pathology
and

G. PANJA, D.BACT. (LOND.)

Assistant Professor of Bacteriology

(From the Department of Bacteriology and Pathology,
School of Tropical Medicine, Calcutta)

MEYER (1940) summarized the facts disclosed by the survey and experimental studies

(Continued from previous column)

districts for the interest and enthusiasm they evinced in conducting the clinical trials, for the infinite pains they took in preparing exhaustive case-sheets, and for the unbiased reports they have made.

Summary

While searching among the indigenous species of the Cassia family for a substitute for *Cassia beareana* which is now being extensively used in the treatment of black-water fever, it was found that a therapeutically active extract could be prepared from the root-bark of *Cassia fistula*.

The extract is prepared by exhausting the powdered root-bark with cold 60 per cent alcohol by the reserved percolate process, the finished product containing 10 per cent by volume of glycerine and representing in every millilitre one gramme of the root-bark.

Out of the series of cases of black-water fever treated with the extract thus prepared, the percentage of cures worked out at 96.3. The urine cleared invariably in 3 to 4 days after the administration of a total quantity of 12 to 16 fluid drachms, the dose given being generally $\frac{1}{2}$ to 1 fluid drachm, repeated every four hours.

Note.—This report is very much more convincing than the usual run of reports on black-water specifics, and the tabular statement of the cases, which we were unable to reproduce on account of shortage of space, adds conviction to the report.

Black-water fever is a disease which seems to be particularly susceptible to cure by 'infallible specifics'. This is possibly because of the variability of the intensity of the attacks.

In a severe attack of black-water fever, there is a sudden very extensive haemolysis of red cells. In an hour or so, all the damage is done. How, in such cases, does the specific act? One might as well look for a specific for a motor car accident! On the other hand, there are cases where the haemolysis is less dramatic but continuous, and the specific may prevent further haemolysis; and yet again there are others in which the damage done by the first haemolysis is not irrevocable, but perhaps nearly so, and the specific may have some unusual diuretic action which makes the damaged kidneys start working again.

There is usually little information, or even suggestion, as to how the various specifics that are advocated for black-water fever act. In this sceptical age, empiricism is at a discount, though we admit that we know little about the action of many useful drugs.—EDITOR, I.M.G.]

(Continued at foot of next column)

conducted by the Hooper Foundation in co-operation with the United States Public Health Service and the California State Department of Public Health since 1933. These conclusions are of such great importance that the relevant sections are reproduced in full below:—

1. That plague of the wild rodents has been definitely recognized in 10 of the 11 Western States at least 1,000 to 1,200 miles inland from the Pacific Coast, the supposed portal of entry. It has invaded the Continental Divide and has been demonstrated close to the Canadian border.

2. That despite the widespread reservoir of plague only 9 human plague infections have been observed between 1933 and 1937; no infections were seen in 1938 and 1939.

3. That at least 18 different species of sciuroidæ, not less than 9 different varieties of citellus, 3 species of prairie dogs, 2 of marmots, 5 of field mice, pack rats and even cotton-tail rabbits were proved as hosts of *Pasteurella pestis*.

4. That *P. pestis* may exist as an inapparent, gross anatomically, even microscopically invisible infection which can be detected only by mass inoculation of triturated organ suspensions of the rodents into guinea-pigs. Latent plague infections were proven in squirrels, chipmunks, golden-mantled squirrels, wood rats, field mice, and flying squirrels.

5. That the invasiveness of the plague strains isolated from these latent infections is undiminished for mice and guinea-pigs, and of the same magnitude as that established for strains isolated from acute and subacute rodent and human infections.

6. That sylvatic plague persists indefinitely in regions in which it has appeared in epidemic form, and that the usual gross anatomical examinations of rodents may not detect the existence of plague.

7. That plague-infected but not necessarily infective fleas are found on a great variety of healthy rodents (even human habitations, donkeys) [sic] trapped or shot in plague areas. Surveys are greatly facilitated by the examination of pools of fleas collected from the rodents. Of the 26 species of fleas found on wild rodents only one-half are capable of transmitting the plague bacillus by bites'.

In view of these important findings a search was made for the existence of latent plague in rodents caught in Calcutta. Wild rats caught in different parts of the city were examined. The methods employed are summarized below:—

Batches of live rats were collected from different parts of the city and killed by 'gassing' with coal gas. Individual batches varied from 8 to 12 rats. Fleas from each batch were collected and the spleens from the rats were dissected out and pooled. Suspensions of crushed fleas and spleens were rubbed on scarified skin (and in the case of the spleen suspensions injected subcutaneously also) into guinea-pigs and mice so that for each batch of rats 2 guinea-pigs and 2 mice were used. Later experiments showed that it was not essential to make dermal inoculations. The animals were observed for 7 to 10 days, when, unless death had occurred previously, the animals were sacrificed and the spleens of the guinea-pig and the mouse were ground up together and injected subcutaneously into a fresh guinea-pig and the animal watched for a week when it was sacrificed. Smears from the spleen of experimental animals were examined and cultures made from each spleen.

ERYTHROCYTE SEDIMENTATION RATE IN CHOLERA

By A. J. H. DEMONTE, D.P.BACT., I.M.D.
and

S. K. GUPTA, M.B., B.T.M.

(From the Calcutta School of Tropical Medicine)

THE erythrocyte sedimentation rate (ESR) has proved of the greatest use in the estimation of the activity or quiescence of chronic inflammatory disease. The mechanism of increase in the sedimentation rate is obscure, but experience has shown that the rate and amount of sedimentation is small when the destructive process is slight, and is markedly increased when the condition is active.

Cholera is characteristically an acute disease, and, though the organism has been known for many years and the disease itself subjected to much careful study, the mechanism of infection and the cause of death is still uncertain. Some claim that the disease is an allergic manifestation and others that it is a toxic process. It was felt that in a disease such as cholera, where there is great loss of fluid with consequent concentration and rise of specific gravity of the blood, the sedimentation rate would probably show no increase; and, conversely, that, if an increase was demonstrated, then the probability that cholera is a toxic process is greater, especially as Wolf (1924) found that the speed of sedimentation of erythrocytes in infants suffering from diarrhoea with toxic manifestation was accelerated, and that, when the diarrhoea was a mere local disturbance without general toxic symptoms, there was no change in the sedimentation rate. It was therefore considered of interest to determine the sedimentation rate in cholera, even though it was

(Continued from previous column)

So far 200 rats collected in 22 batches have been examined with negative results for *P. pestis*; *P. septica* was isolated from two batches of 7 and 10 rats and *Bacterium typhimurium* (*œrtrycke*) from three batches.

Summary

Attention is drawn to the importance of latent plague in rodents and that infection of rodents with *P. pestis* can occur without any apparent gross lesions. This latent infection can be detected only by animal inoculation experiments. Although the results of the examination of a series of 200 rats have been negative for *P. pestis*, the findings of the work carried out in America are of sufficient importance to stress the necessity of further work on these lines. Further this survey must be extended to include other rodents.

likely that the test would have no specific significance in diagnosis.

Technique.—Westergren's sedimentation apparatus was used. Exactly 0.4 c.cm. of a 3.8 per cent solution of sodium citrate in distilled water was drawn into a record syringe the needle of which was then introduced into a vein and blood drawn up to the 2 c.cm. mark. A tourniquet was used to facilitate venepuncture, but it was immediately released as soon as the needle was in the vein. The blood-citrate mixture was transferred to a sterile $4 \times \frac{1}{2}$ inch test-tube and the test was put up within half an hour of collection.

The citrated blood after careful mixing was drawn up into a Westergren pipette which is calibrated in millimetres from above downwards so that the zero mark is exactly 200 mm. from the extreme point. The blood was drawn up to the zero mark, care being taken to avoid bubbles, and the pipette was placed vertically in its stand. The level of the red cell column was read after 1 and after 2 hours, so that the readings taken indicate the distance the erythrocytes sedimented from the zero mark in that time. The tests were performed at room temperature which averaged between 31 and 33°C.

Blood from 79 male cases of cholera was collected within 12 hours of admission to the cholera ward. In 21 of these the test specimen was taken immediately on admission and before any treatment had been administered; in 34 cases the blood was collected within 4 hours and in 24 within 12 hours of admission to the ward. In the latter two groups, hypertonic saline had been administered intravenously 1 to 3 hours previously to the patients in the first group and between 10 and 12 hours in the second group of patients.

No corrections on account of cell volume, haemoglobin percentage, erythrocyte count, viscosity, temperature, etc., have been made. The haemoglobin percentage of the first six cases was determined and found to be above 100 per cent in five and 84 per cent in one with the Hellige haemoglobinometer; the erythrocyte count of the same six cases averaged from six to seven millions per c.mm.; also a few samples were put up for the sedimentation rate in parallel series, one being kept on the bench at room temperature and the other in the incubator at 37°C. No appreciable difference was noted in the erythrocyte sedimentation rate of the two series. These additional tests were done with a view to making corrections for these factors, but it was discontinued as it was considered illogical to correct for one or two factors while ignoring others. But controls were put up at the same time so that whatever personal and climatic errors influenced the tests influenced both equally. In this way a standard for comparison was obtained from 20 apparently healthy males which included Bengalees (16), Anglo-Indians (2) and Punjabis (2). The majority of these

were laboratory workers and post-graduate students.

The erythrocyte sedimentation rate of 17 of these apparently healthy males was 2 to 7 mm. in the first hour and 3 to 18 mm. in the second hour. The rates of sedimentation in the remaining three, who by clinical examination appeared to be perfectly healthy, though thin and slight of build, differed greatly from these and were 18 to 25 mm. in the first hour and 42 to 50 mm. in the second hour.

We have, therefore, some difficulty in fixing the ESR for normal healthy Indians. Muir (1929) reports that the sedimentation rate for normal Indians according to his technique was 10 mm. and 20 mm., the readings being taken $1\frac{1}{2}$ and $2\frac{1}{2}$ hours after setting up. Pasricha *et al.* (1941) report a range of 2 to 18 mm. (uncorrected) and Napier and Das Gupta (1941) 2 to 15 mm. in the first hour. If the mean and the standard deviation of the ESR of all the 20 apparently healthy Indians estimated by us is taken, then the figures obtained would be 20 mm. and 44 mm. for the first and second hours, respectively. If we were to accept these figures, the ESR of two of the exceptional individuals would still be outside the limits fixed as normal. But is one justified in including in a series such as this, where one is endeavouring to establish the sedimentation rate of *normal* healthy people, figures which by the standard obtained would be considered as abnormal? Under the circumstances, it has been decided to exclude these three individuals and the five cholera patients whose ESR were estimated at the same time.

Taking therefore as our standard for comparison the results obtained by the examination of the 17 apparently healthy people, namely, 2 to 7 mm. for the first hour and 3 to 18 for the second hour, the following results were obtained when the ESR of the 79 male cholera patients was estimated :—

TABLE I
Giving the results of the ESR of 79 cholera patients : First hour readings

	Number
ESR did not exceed 7 mm.	.. 26
ESR was between 8 and 14 mm.	.. 20
ESR was between 15 and 28 mm.	.. 17
ESR was between 29 and 60 mm.	.. 12
ESR was above 60 mm. 4

It appears, therefore, from the results given in table I that the ESR in cholera is accelerated and the total fall is greater than that for healthy individuals in 53 (67 per cent) of 79 cases. In the remaining 26, which includes all types of clinical cholera, the ESR was apparently normal. Analysing these results further according to bacteriological findings, clinical condition, specific gravity of the blood and the influence of saline, we find that with the exception of the specific gravity of the blood there was no

special relationship with any of the above factors and the sedimentation rate.

It is evident that the presence or absence of vibrios has very little influence on the sedimentation rate. This is in agreement with the findings of other workers for other diseases, *viz.*, that the test is not diagnostic.

The degree of the severity of the disease appears to have little influence on the sedimentation rate. There is apparently an increase in the sedimentation rate when there is toxic manifestation, but the degree of the increase does not increase *pari passu* with the severity of the attack. On the other hand, in

TABLE V
ESR in relation to administration of saline intravenously

	Not above 7 mm.	Between 8 and 14 mm.	Between 15 and 28 mm.	Between 29 and 60 mm.	Between 61 and 100 mm.
No saline ..	7 (33.0%)	5	6	3	..
Saline given 1 to 3 hours previously.	11 (32.4%)	9	5	6	3
Saline given not earlier than 10 hours previously.	8 (33.0%)	6	6	3	1

this disease, the more severe the attack the greater the likelihood of the patient developing a high specific gravity of the blood with consequent slowing of the sedimentation rate. This is well illustrated in table IV.

The numbers in each group are much too small to allow of any deduction being made, though it is tempting to point out that, as the blood specific gravity of the cases rises, the number showing no acceleration of the sedimentation rate steadily increases. How far the rate is affected by the great loss of body fluid and the increased viscosity of the blood, we are unable to say. The cell volume of the blood of the patients with specific gravity 1064 was estimated and found to be from 60 to 66 per cent.

In two other patients not included in this analysis, blood for sedimentation was collected from one arm while hypertonic saline was being administered intravenously in the other. The sedimentation rate was 143 and 67 mm. for the first hour and 155 and 93 mm. respectively for the second hour. In table V it will be noticed that of the four patients whose ESR was between 61 and 100 mm. in the first hour, three had received saline 1 to 3 hours previously and one 12 hours previously, so that it led one to examine more closely what influence the administration of saline, intravenously, 1 to 3 hours previous to the collection of the sample had on the sedimentation rate. It will be observed that the percentage of cases showing no acceleration in the ESR in the group that received saline 1 to 3 hours previously is practically the same as that obtaining in the other two groups. The administration of intravenous saline, therefore, to male cholera patients 1 hour or more prior to collecting blood for ESR appears to have little effect on the sedimentation rate.

Summary

The ESR of 79 male cholera patients was estimated by the Westergren method.

There is an increase in the sedimentation rate of 53, or 67 per cent, of the 79 patients tested.

The higher the specific gravity of the blood at the time of testing for the sedimentation rate the greater is the number showing no increase in ESR.

Note.—The ESR of three of the controls that were excluded was repeated 2 years later; one was found to be 5 and 15 mm., the second 16 and 39 mm. and the third 8 and 20 mm. for the first and second hour, respectively. This last control is now known to be a diabetic responding well to dietetic treatment.

THE STERILITY AND POTENCY OF INJECTABLE SUBSTANCES

(ii) SALINES FOR INTRAVENOUS USE

By C. L. PASRICHA

MAJOR, I.M.S.

Professor of Bacteriology and Pathology

K. S. MALIK

and

B. M. PAUL

(From the Department of Bacteriology and Pathology,
School of Tropical Medicine, Calcutta)

ALTHOUGH it has been conclusively shown by a number of workers that it is possible to avoid febrile and other undesirable reactions following parenteral medication, this is not realized by many clinicians and others responsible for the preparation of solutions intended for intravenous use. The reactions (characterized by chill and fever and at times even profound collapse) that occur after intravenous injection of salt solutions are dismissed as 'injection reactions', 'saline reactions', or 'non-specific', and are explained on various obsolete, complex, and unsubstantiated theories involving the doctrine of specific ion effect, haemolysis, hydrogen-ion concentration, etc., or more often simply regarded as inevitable after-effects of intravenous therapy. It must be remembered that sodium chloride, sodium bicarbonate, or other ingredients present in different kinds of salines are physiological substances normally present in the blood stream and tissues of the human body, and have been shown, by themselves in the concentrations used, to cause no ill effects.

Recent work has shown that it is the water in which the various ingredients are dissolved that is the least suspected but often the most consistent cause of these reactions. Although it has been known for many years that intravenous injections of distilled water into animals may cause febrile reaction, it was not till the extensive and well-planned investigations of Hort and Penfold (1911) and later of Seibert (1923) that the nature of the fever-producing substance in water was discovered. These workers demonstrated that the reactions, following parenteral medication were due to 'contamination products' in the water used for the preparation of the solutions. A substance named 'pyrogen' (fever producer) was shown to be split protein products of certain bacteria which present in the air gain access to and rapidly multiply in water that is not kept absolutely sterile. The pyrogen develops rapidly and may be found in 2 to 4 days in distilled water kept in the ordinary open or partially open laboratory jars or containers. The pyrogen is soluble, filtrable, and thermostable except at very high temperatures. Further, unless scrupulous care is taken, pyrogens already present in the water that is being distilled can pass over with droplets

of water during distillation. To obtain water free from pyrogens it must be distilled in a still fitted with adequate arrangements to prevent the pyrogenic substances from being mechanically carried over into the distillate. Seibert (*loc. cit.*) has shown that all waters do not produce fever on injection and that there is a seasonal variability. Tap waters in certain seasons always cause fever whereas at other seasons they do not do so with the same regularity. Carter (1930) advocated a method of estimating pyrogen in water. This method (using potassium permanganate) which is based on the well-known principle of estimating organic matter in water has been shown by Banks (1934) and others to be not a true index of the pyrogen content. The most satisfactory method for the detection of pyrogen and the estimation of pyrogenic activity of water is by ascertaining the rise in rectal temperature of rabbits injected intravenously with measured amounts of water under test.

The importance of these observations in practical therapeutics has been realized by a number of workers and several methods of the preparation of pyrogen-free water have been advocated. Thomas and Ting (1938) stress the importance of pyrogen-free water in the preparation of saline for intravenous use in cholera patients. They describe a method of preparation which is both simple and cheap, and record 570 intravenous infusions of saline and glucose prepared with pyrogen-free water without a single untoward reaction. Injections were also given to over 1,600 cases of cholera without producing any reactions—a most creditable result. Keller

(1937) gives details of his method of preparation of saline. The method is efficient and economical, and the average time required for preparing 32 litres of saline solution, from the start to the capped bottled product, is approximately 3 hours. More recently Lees and Levvy (1940) describe a method for the emergency preparation of pyrogen-free water. The water is shaken for 15 minutes with powdered charcoal (1 gramme of charcoal per litre of water). The charcoal is then separated by decanting through a filter paper. This procedure is claimed to remove pyrogens from even heavily contaminated water.

In order to ascertain the quality of locally prepared salines intended for intravenous use, 12 samples of such salines were examined. The samples in original bottles or other containers were collected from those in actual use or issued for use. The sterility and the presence of oxidizable matter were first examined. As the results showed heavy bacterial contamination and the presence of comparatively large amount of oxidizable matter, the 'rabbit test' for pyrogen was not carried out with all the samples and is therefore not recorded.

The test for oxidizable matter was done according to a slight modification of Carter's method for pyrogen. A hundred cubic centimetres of water are heated in a scrupulously clean beaker (pyrex) and acidified with 10 c.cm. of 10 per cent sulphuric acid. The addition of 0.2 c.cm. of N/50 potassium permanganate imparts a pink colour to the mixture. If after boiling for 10 minutes the pink colour remains, the sample is pyrogen-free. The disappearance

Results of the examination of 12 samples of salines intended for intravenous use

* The glass stoppers in these two bottles were a mere excuse for a covering for the bottle. The bottles were not designed for use with glass stoppers. The glass stoppers were lying loose in the necks, and rattled on shaking the bottles. Bottles nos. 8 to 12 were of cheap quality of the type generally used for filling with kerosene oil.

of the colour indicates the presence of organic substances in the water. In the tabulated results is given the amount of N/50 potassium permanganate that it was necessary to add to each sample so that a definite pink colour persisted after 10 minutes of boiling of the mixture.

The organisms isolated were cocci of various types and the common sporing bacilli of the subtilis-mycoïdes group. From one sample Gram-negative bacilli were isolated. The number of bacteria in the different samples was not estimated, but all the samples gave positive results when 1 c.cm. of the saline was used as inoculum. The isolation of the inagglutinable vibrios was made from inoculums of 5 c.cm of the sample in peptone water. Both these samples of saline had been obtained from cholera wards.

Experiments designed to determine the source of oxidizable matter gave results which confirmed Seibert's findings and therefore need not be detailed here. The only additional point noted was that when the saline is distributed in cotton-plugged bottles or flasks and sterilized in the autoclave then a certain amount of oxidizable matter is found in the saline. This is derived from the cotton-wool. Similarly, if the saline is filtered during any stage of its preparation through cotton-wool then an appreciable amount of oxidizable matter can be detected in the saline.

Further comment on these results is unnecessary except to state that improvements in the methods of preparation, sterilization and storage in containers which will ensure sterility is necessary. The ordinary type of bottle with a glass stopper (unless the neck is protected by paper covering) is unsatisfactory. The simplest and cheapest method is to use screw-capped bottles in which the chances of contamination occurring at the mouth are minimized.

It would appear highly desirable to arrange for a central source of supply of saline intended for intravenous use. These centres which must be in charge of a competent staff would ensure the regular supply of saline and other products prepared from pyrogen-free water. It has been conclusively shown that distilled water kept under ordinary conditions is not necessarily as pure or as physiologically harmless as is usually supposed. This point cannot be emphasized too much or too frequently as it has been repeatedly demonstrated that pyrogen is the greatest and most constant single factor in the cause of reactions. Pyrogen can be eliminated by present-day methods and there is no need to run the risk of causing untoward reactions and of burdening the body. The intravenous use of saline has been termed 'life saving' in cholera, but with bad salines the results may not be so satisfactory. Thomas and Lih-Cheng Ting in discussing the importance of freshness of salines state 'the reports we have received from these

(Continued at foot of next column)

A FURTHER TYPE OF CHOLERAPHAGE —TYPE N

By C. L. PASRICHA
MAJOR, I.M.S.

Professor of Bacteriology and Pathology
M. N. LAHIRI
and

A. J. H. DEMONTE, I.M.D.

(From the Department of Bacteriology and Pathology,
School of Tropical Medicine, Calcutta)

In 1929, d'Herelle, Malone and Lahiri (1930) described three different races of choleraophage; these were carefully studied and named types A, B and C by Asheshov (1930). Two years later, Pasricha, deMonte and Gupta (1932 and 1932a) reported three additional types (D, E and F) which were soon followed by types G, H and J reported by Morison (1933), and type K by Pasricha (1933). Type L was added to the list of choleraophage types by Anderson (1935), and a year later type M was described by Pasricha, deMonte and Gupta (1936). White (1937) in studying a choleraophage type (type L isolated in Calcutta and sent by one of us) came to the conclusion that it differed from the original type L of Anderson and in order to avoid confusion named it choleraophage LL. White made the interesting observation

(Continued from previous column)

areas (areas at a distance and where fresh solutions were not available) that the response to injection was directly related to the freshness of the distillate. In one village the impression was that the mortality was higher in those infused than among the untreated'.

Summary

The results are recorded of the examination of 12 samples of saline intended for intravenous use. These samples were picked up at random from those in actual use or issued for use.

All the 12 samples contained viable bacteria and comparatively large amounts of oxidizable matter.

Suggestion is made for the establishment of central laboratories that will undertake the preparation of pyrogen-free distilled water and salines for intravenous use for distribution. That there is a need for such a central organization is stressed by the results recorded.

that egg-white lysozyme (egg-white used in 1 in 25 concentration) itself, without appreciable effect on the growth of the normal cholera vibrio, so enhances the activity of LL phage that visibly active filtrates may be obtained with regularity. Using this method, White found that all the fifteen Indian strains of *Vibrio cholerae* examined by him were infected with LL phage, whereas ten Chinese and Japanese strains of *V. cholerae* proved free of LL phage and were sensitive to its action. White also drew the attention to the possibility that LL phage was the most frequently occurring of Indian choleraphages and the probability that all the then-current choleraphage types were contaminated with LL phage.

In order to establish the exact nature of the choleraphage LL, a set of choleraphage types A to M was 'purified' from the contaminating LL phage by propagation and 'plaque isolation' on a Japanese Inaba strain of *V. cholerae* which was known to be free from any contaminating LL phage. A 'reciprocal cross-test' was done and phage LL behaved as a new type, the secondary culture obtained after the action of phage LL is lysable by the other twelve types (A to M) and LL phage acts on the secondary cultures obtained after the action of each of the other types. Because of this reciprocal activity LL phage is a new type of choleraphage and should be known as type N, thus bringing the known number of choleraphage types to thirteen.

Type N choleraphage resembles type A and stands out from types B to M in that it acts only on agglutinable vibrios (but not on the El Tor strains—ten such strains tested) and has no action on inagglutinable vibrios (165 inagglutinable strains isolated from cholera patients and waters tested). Because of its restricted action on *V. cholerae* type N is an important type for further study particularly as to its value in the classification of *V. cholerae*.

A series of 115 freshly-isolated strains of *V. cholerae* were examined for the presence of contaminating phage, and type N was found in only three of these strains. It must be noted, however, that the strains tested were all isolated within a short period and during the height of a cholera epidemic. Thirty old laboratory strains of *V. cholerae* were all contaminated with type N. These strains had been maintained for some years in the laboratory and included the strains examined by White. Five strains of *V. cholerae* from Hong Kong were examined for contaminating phages and three yielded type N, two were free, one of these was resistant and the other sensitive to the action of type N.

Type N choleraphage varies greatly in its activity, some races are feeble and unstable, and some produce a marked effect, but all belong to one type. This type appears to be best propagated either in the presence of egg-white lysozyme, or on solid or semi-solid agar.

AN INSECTARY COLONY OF
A. STEPHENSI MYSORENSIS*
By PAUL F. RUSSELL
and
BADRI NATH MOHAN

SWEET and RAO (1937) separated *A. stephensi* of Mysore into two biotypes, called *A. stephensi* (type) and *A. stephensi* var. *mysorensis*, on the basis of egg patterns. These observers found that the type form had larger measurements of ova as regards length, greatest breadth (including floats), number of ridges on float, and the proportion of the total length which is covered by the floats. They also noted that while the type *stephensi* was easily colonized, *mysorensis* failed to establish itself. The *mysorensis* females could not be induced to oviposit.

*The observations on which this note is based were carried out as a part of the programme of Malaria Investigations, under the auspices and with the support of the International Health Division of the Rockefeller Foundation co-operating with the Health Department of Madras Presidency, the King Institute of Preventive Medicine in Guindy, Madras, and the Pasteur Institute of Southern India in Coonoor.

(Continued from previous column)

Its further characters and its frequency in nature have not been as yet worked out.

Summary

Choleraphage LL described by White possesses reciprocal action and is therefore a new type. In conformity to the nomenclature adopted for the naming of choleraphage types it is suggested that it be known as type N—the thirteenth type of choleraphage so far isolated.

Type N is an important type in that it acts only on *V. cholerae* and not on the inagglutinable vibrios. In its action which is restricted to *V. cholerae* it resembles type A.

We obtained some larvae of *mysorensis* from Sweet and Rao and compared the adults with some of the type forms from our insectary colony as regards susceptibility to experimental malaria finding no significant differences (Russell and Mohan, 1939).

We had had no difficulty in carrying along a colony of the type form (Russell and Mohan, 1939a) but failed in our first two attempts to colonize variety *mysorensis*. Obtaining a third lot of *mysorensis* from Dr. B. A. Rao, sent to Madras from Mysore, we have been able to colonize the variety. The purpose of this note is to report this success together with the significant fact that practically the same egg differences have appeared clearly through nine colony generations of *mysorensis* and about 60 generations of type *stephensi* (see table).

At first there was also some difficulty in getting male *mysorensis* to fertilize the females. Therefore we kept individual males and females in vials for several days, feeding the former on 10 per cent glucose water and the latter on rabbit blood. Numbers of celibate males and chaste females were then put together in a colony cage and mating occurred without much delay.

When, following this forcing technique, the first generation had gone through the aquatic stages and had emerged as adults, there was considerably less reluctance to mate and to oviposit and we have not found it necessary to repeat the special technique. The colony has progressed uneventfully through nine generations. Our colonizing technique has been fully described elsewhere (Russell and Mohan, 1939a).

TABLE
Measurements of ova of *A. stephensi* type and variety *mysorensis*

Description	TYPE		<i>Mysorensis</i>	
	Present report	Sweet and Rao (1937)	Present report	Sweet and Rao (1937)
Length	540 ± 7.0	555 ± 24.0	500 ± 18.0	476 ± 24.0
Breadth	210 ± 4.0	204 ± 12.0	182 ± 9.0	160 ± 12.0
Number of ridges on floats	18 ± 1.1	18 ± 1.6	14 ± 0.8	13 ± 1.2

Note.—Length and breadth are given in microns. Breadth is greatest measurement, including floats. Sweet and Rao (1937) gave mean measurements expressed to two decimal places. In the above table they have been rounded off. The present report is based on 80 observations.

We found at first, in our third lot, the same reluctance on the part of *mysorensis* to lay eggs and therefore resorted to force to obtain ovipositing. Individual gravid females of *mysorensis* were placed in test-tubes. The side of a tube was gently knocked a few times and then, by vigorously swinging the tube, the female was flung into water in a petri dish inside a colony cage. If the legs of the insect became entangled in the water it usually began at once to oviposit. If not, it would fly upwards and the measure would be repeated. When ovipositing was completed the insect was lifted out on filter paper and it would fly to the side of the cage when the paper became dry.

Summary

A. stephensi var. *mysorensis* (Sweet and Rao, 1937) has been successfully colonized through nine generations and the distinctive ova measurements, which differentiate this variety from *A. stephensi* type, were observed in the ninth generation.

A Mirror of Hospital Practice

TREATMENT OF A CASE OF SMALL-POX WITH SULPHONAMIDE-P

By N. G. CHAKRABARTY

Assistant Medical Officer, Gairkhatia Tea Estate, Dooars, Gairkhatia, Jalpaiguri District

A TEA GARDEN female labourer, aged 25 years, parity 5, delivered a male child normally on 11th May, 1940 (evening).

I attended her next day and found nothing but usual pelvic pain. The child was healthy. On 13th May, she had pain over the breasts and slight headache. Temperature 100°F., pulse 90, respiration 20 at 2 p.m. Bowels moved once, passed urine three times, tongue slightly coated and moist. I took it for 'milk fever'. I gave her one A.P.C. powder. Next morning she felt better but complained of backache. Temperature 98.4°F., pulse 88 and respiration 20 at 10 a.m.

On 15th May she had no fever but slight pain all over the body. Temperature 98.2°F., pulse 84,

respiration 22, tongue slightly coated and moist, spleen and liver not palpable, lungs and heart normal.

On 16th May she had fever with severe headache and pain all over the body. I was informed in the evening and attended her at 7 p.m., when she had temperature 99°F., pulse 100, and respiration 26. As there was a case of small-pox next door a fortnight earlier and there was an epidemic in this district I suspected it to be a case of small-pox but could not find any eruption owing to insufficient light. The child was well.

On 17th May I attended her at 9 a.m. when she had temperature 101°F., pulse 100, and respiration 28. I found the following:—Severe pain all over the body, swollen face with shotty papules. These were also present over the arms and legs but none on the chest and abdomen. I removed her to a segregation house with all her contacts immediately. The medical officer kindly attended her and confirmed my diagnosis saying that the duration was not more than 36 hours. With his advice I gave her two tablets of sulphonamide-P at 2 p.m. when she had temperature 102°F., pulse 110, respiration 30.

Two tablets of sulphonamide-P were repeated thrice daily for five consecutive days. Temperature began to come down after the first dose but pain continued till next day. At 6 p.m. temperature 101.4°F., pulse 108, respiration 32, and at 10 p.m. temperature 101.2°F., pulse 104, and respiration 32.

On 18th May the patient began to feel a little better. I found prominent vesicles on the face, arms and legs. They were circular and umbilicated.

At 6 a.m.	temperature	98.6°F.	pulse	96,	respiration	26
10 "	"	98.4°F.	"	94,	"	26
2 p.m.	"	98°F.	"	94,	"	26
6 "	"	98°F.	"	94,	"	26

On 19th May the patient felt much better, slight pain was present. Temperature sub-normal, pulse 90, respiration 24.

On 20th May the patient was getting better gradually. Temperature sub-normal, pulse 84 to 82, and respiration 20. I noticed that the vesicles of the face began to shrink a little; it was the fourth day.

From the next day all the vesicles began to shrink without pustules. Scabs began to form on the sixth day and they were complete by the ninth day. She had no rise of temperature. She was declared cured and discharged when all the scabs were fallen. She had no deep marks.

The points of interest

In this case temperature did not rise more than 102°F. on the second day when papules were seen. Temperature began to come down after the first dose of sulphonamide-P. There were no pustules. She had no secondary rise of temperature. Papules and vesicles were earlier. No deep marks were left after cure. It is to be noted that the patient was vaccinated a fortnight prior to her illness. Although the child was allowed to suck, he escaped the infection. The child was not vaccinated.

If it be taken into consideration that the disease started on 13th May, 1940, when I took it for 'milk fever' then why did the temperature come down to normal without any eruption?

Is this case modified by previous vaccination or the action of sulphonamide-P?

I should thank Dr. E. B. Rogers, the medical officer, and Mr. J. J. Macpherson, the manager, for their kind permission to allow me to report this case.

VIPER VENOM IN A CASE OF RECURRENT HÆMORRHAGE IN THE VITREOUS

By K. N. PRADHAN, L.M.&S. (Bom.), B.S.E. (Nag.)
and

N. G. PATWARDHAN

'Krishna Bhavan', Humpyard Road, Sitabuldi, Nagpur,
Central Provinces

R. P., aged 50, a retired clerk, came to me walking with the help of his daughter, for total loss of vision in right eye and very little vision in left eye.

History.—The patient gave a history of having exposed himself to infection in May 1935. A copper coloured rash appeared in September 1935. He had neosalvarsan 0.15, 0.35, 0.75 gramme injections, at one-week intervals. Dermatitis and urticaria appeared after the second injection; still the course was continued with the result that he developed general oedema. Dermatitis was increased to weeping eczema, and the skin began to darken. He gave up this treatment, and started taking Ayurvedic medicines, when all these troublesome symptoms subsided. He took calcium lactate in December 1935 and believed that he was completely cured by April 1936. In June 1936 he got an attack of iritis in one eye; loss of vision in the other eye together with ataxia and constant urge to urinate also was noticed at this time. Urine when examined was found to contain albumin and pus cells. His eyes cleared under atropine and dionin. In 1937 iritis recurred and this continued till November 1938.

On examination.—Right vision: only projection of light. Left vision: fingers at one foot only. No conjunctival irritation, cornea in both eyes clear. In left eye pupil was contracted to 5 mm. due to adhesive iritis, no accompanying symptoms, no rise of tension in either eye.

Dark-room examination.—No red reflex in right eye. Perception of light was so poor that he could not see the bright nickel handles of the pantostat.

Diagnosis.—Right eye: vitreous haemorrhage. Left eye: adhesions due to iritis; all due to syphilis.

Since November 1938 up to the date of report 18th November, 1940, he has been under my observation. His Wassermann reaction was done and found to be ++++. Urine trouble continued but no albumin, no sugar, no pus cells. For nearly one year he had the following treatment:—

Atropine and dionin in the eyes; right eye always dilated easily and fully, sub-conjunctival injections of normal saline, mercury inunctions, injections of bismuth preparations, Donovan's solution by mouth, and salicylic ionization for the eyes. Ataxia was noticed to be less after each ionization. No improvement in left eye. Vision in right eye improved to counting of fingers at 5 feet. Red reflex appeared. Trouble over urine continued till November 1939.

Though I knew that he had an idiosyncrasy for arsenic, in desperation, I gave him one injection of an arsenic preparation intramuscularly, novarsan 18 centigrammes. He again had all the symptoms of intolerance of arsenic previously noticed. But this time they were cured within a fortnight by salicylic ionization for skin trouble, calcium lactate and potassium iodide by mouth, and emetine injections. Vision in right eye improved to fingers at 10 feet but no change in left eye. Glasses were tried but they did not improve vision in either eye. In April 1940 he had haemorrhage again in right eye (the same eye), red reflex was gone and vision was reduced to perception of light only.

As he had every kind of treatment that was indicated we were thinking if anything else could be given to prevent his total blindness in due course, when the

junior author suggested trying viper venom which was given as follows:—

Injections	Date, 1940	Doses, c.c.m. (1 in 1,000)	Symptoms 24 hours after the injections
1st	7th June	0.1 diluted.	No local or general reaction.
2nd	11th June	0.2	Sense of well-being was reported, no reaction.
3rd	18th June	0.5	Temp. 101°, stiffness in legs, eye became very red, but the haemorrhage was being absorbed as better view of the fundus could be obtained.
4th	25th June	0.6	More reaction both local and general.
5th	10th July	0.8	No trouble at all.
6th	25th July	0.8	Do.
7th	9th Aug.	1.0	Do.
8th	24th Aug.	1.0	Do.

At the end of August the right eye completely cleared up, but there was no change in the left.

Our findings on 17th November were as follows:—

Right eye—Conjunctiva clear; cornea clear; pupil dilated easily; anterior chamber clear; no signs of iritis.

Fundus reflex—Greyish, vitreous opacities—white bands seen running transversely and vertically.

Disc—Colour yellowish red, margin clear, lamina cribrosa not seen clearly, vessels—arteries have become very thin, veins more prominent by contrast. Macula—a little pale, and blackish deposit round about. Vision—6/12 and with +2.50 J 3.

Left eye—Fingers at 2 feet. This eye is not useful.

General examination—Urine clear, blood pressure 135–85. Ataxia less, urinary frequency much less, no albumin, sugar, casts, or pus cells.

The rationale of snake venom in therapy (Chopra, 1936).—It contains the following active principles:—(a) Neurotoxin, (b) cytolysin and absorption of granulation tissue, (c) coagulative and haemorrhagic enzymes, and (d) protective properties against rabies and epilepsy.

We are here mainly concerned with the cytolysin and coagulative enzymes, the two active principles. On account of the presence of these, venom possesses the property of absorbing granulation tissue and neoplastic protective cells, formed in the tissue, and it has been shown to retard the growth of tumour and cause metastasis to disappear. On account of the presence of coagulative enzymes it has been used in the treatment of menorrhagia, bleeding piles, purpura and haemophilia.

We have not so far seen any reported case of recurrent haemorrhage in the eye cured by means of snake venom. We therefore submit that on account of its coagulative property it checked further haemorrhage and caused rapid absorption of the blood clot on account of its cytolysin and absorption of granulation tissue.

Summary

1. Eye infection started differently in the two eyes, in one iritis, in the other vitreous haemorrhage, after one year of infection.

2. Antisyphilitic treatment for want of arsenic tolerance could not be pushed to its full effect.

3. Recurrence of haemorrhage in the same eye.

4. Absorption of haemorrhage from a body, in which there are no direct blood vessels, by Russell's viper venom, total 5 c.c.m. of 1 in 1,000.

Conclusion

The injections of venom not only checked further haemorrhage in the vitreous but caused a rapid absorption of the existing blood clot, and thus restored useful vision to the patient. We are aware of the fact that a solitary case only is quite insufficient to draw a general conclusion but we hope that others who have more opportunities will give a trial to it and thus help to come to a final conclusion.

A CASE OF SCARLET FEVER

By H. L. MALHOTRA, M.B., B.S., D.P.H. (Lond.), D.T.M. (L'pool), T.D.B. (Wales)

Municipal Medical Officer of Health, Rawalpindi

RAKSHA, aged 7, had been having throat trouble for some time. Tonsillectomy was advised and it was suggested that she should have a course of sulphonamide before operation. In the last week of July, eight tablets of proseptasine were administered. Any idea of operation was given up for the time being and proseptasine was stopped. From the 27th to 30th August, eight tablets were again administered. She had low fever off and on. On 4th September the temperature was 100°F. with complaints of headache and pain in abdomen. There was constant and severe sore throat with marked dysphagia and furred tongue. Throat examination showed tonsils red and enlarged with follicular spots.

5th September.—Constipation; temperature rising up to 103°F., abdominal pain, dysphagia, exudate involving the anterior pillars of the fauces and back of the throat. Tongue furred showing reddened papillæ. A typical rash appeared—red flushed skin with punctate erythema; marked circum-oral pallor; very severe itching; and fairly severe vomiting. Fever, rash and vomiting with the previous history suggested sulphonamide poisoning and the throat condition made one think of diphtheria. Throat swab easily removed the exudate from follicles and the smear under the microscope was not suggestive of diphtheria. It showed chains of streptococci. Total leucocyte count was 12,000 per c.mm., differential count—polymorphonuclears 79, lymphocytes 13 and large mononuclears 8 per cent, thus agranulocytosis, a marked feature of sulphonamide poisoning, was ruled out. There was also absence of cyanosis.

Thinking over the whole case, signs and symptoms suggested scarlet fever to me but I could not reconcile it with prophylactic administration of sulphonamide. On questioning the doctor who made the differential count, I was informed that he did see a few eosinophils also. Blood picture, condition of the throat and tongue, rash and circum-oral pallor strongly pointed towards scarlet fever. Two other doctors attending the patient, however, did not agree.

6th and 7th.—Range of temperature 103°F. to 105.5°F. Severe itching, constipation, pain in abdomen,

backache and dysphagia were present. Tongue—tip and edges red and clear but otherwise coated, red papillæ prominent—a typical white-coated strawberry tongue.

8th.—It was on this day that typical clear red-strawberry or raspberry tongue was seen. Fur had all peeled off leaving a clear tongue with prominent papillæ. In the flexures of the elbows transverse lines of pigmentation in the creases of the skin were noticed and appearances suggestive of punctate haemorrhage in the flexures of the elbows were also observed. At this stage we all agreed that it was a case of scarlet fever. Rash was not intensive or of long duration. Desquamation started by the end of the first week of illness.

Temperature touched normal on the morning of the 11th with a little rise in the afternoon but remained normal throughout on the 12th. In the 4th week of September epidermis of hands and feet was still peeling off. The patient being my own daughter and treated at home, it was possible for me to make detailed observations.

On 17th September, I was called in to see another similar case which showed all the clinical signs of scarlet fever. Source of infection could not be traced. In February 1940, one case of scarlet fever was reported occurring amongst British troops who had just arrived from the United Kingdom and were proceeding to Waziristan. In April, two cases of scarlet fever were reported amongst British troops in a different regiment. Diagnoses were based on clinical findings. No connection is traceable between the three cases occurring in Rawalpindi cantonment and the two cases occurring in September in the city.

No bacteriological or serological examination could be made.

It is believed that scarlet fever does not ordinarily occur in India. Municipal medical officers of health of Amritsar, Multan, Sialkot, Jullundur, Ferozepore and Ludhiana were asked if they had ever come across a case of scarlet fever in their towns, and all replied in the negative.

In 1924 the Director of Public Health, Punjab, reviewing the position in the Punjab concluded:

(1) The disease is apparently not endemic in either the hills or the plains of the Punjab.

(2) The rare instances in which scarlet fever has been detected in the Punjab have invariably been among Europeans, or Indians in closest contact with them; in the two cases reported no connection with Europeans could be traced.

(3) There is sure evidence that the disease is occasionally imported into the Punjab from abroad through the agency of postal matter; in the two cases reported no such connection could be traced.

(4) There is no known instance of importation of infection being followed by an epidemic amongst the indigenous population.

Scarlet fever is one of the group of widely different diseases the causative organism of which is a haemolytic streptococcus. Haemolytic streptococci are divided into types some of which are pathogenic to man but none of the conditions comprising the group of widely different haemolytic streptococcal diseases is

due to one type only. Scarlet fever in one patient may be due to type 1, in another to type 2 and in a third to type 4. Scarlet fever and puerperal fever may be due to the same type. The group is composed of scarlet fever, infectious sore throat, erysipelas, and puerperal fever. The mode and portal of entry of the organism, general and local tissue resistance of the patient, invasive power of the infecting type of organism and its capacity to throw out rash-producing exotoxin, as well as susceptibility and resistance of the skin of the patient to this exotoxin, determine the clinical syndrome.

When a pathogenic type of haemolytic streptococcus, capable of producing erythrogenic exotoxin, invades the fauces in a patient whose skin is susceptible, the clinical syndrome produced is the ordinary scarlet fever. The only difference between acute infectious tonsillitis produced by haemolytic streptococcus and scarlet fever is the absence of the skin rash. This may be due to either resistance of the skin of the patient—shall I say Dick negatives—or feebleness of the haemolytic streptococcus in producing erythrogenic exotoxin. Acute infectious tonsillitis is, I believe, pretty common. Rarity of scarlet fever may be accounted for by—

- (1) Resistance of the skin of Indians, i.e., a very high percentage of the Dick negatives.
- (2) Rarity of the pathogenic strain of haemolytic streptococcus capable of producing erythrogenic exotoxin.

The first is a problem for the public health worker to investigate and the second would be answered by a bacteriologist. I am informed that in 1937 some American authority got Dick tests done in the Mayo Hospital, Lahore, showing 34 per cent positive. I understand that toxin for carrying out further tests at the present moment is not available. Typing of haemolytic streptococci requires typed sera. In the Punjab only the Research Institute, Kasauli, possesses these typed sera where typing is done.

SPONTANEOUS PNEUMOTHORAX WITH A PLEURO-PERITONEAL FISTULA

By P. K. GHOSH, M.B., D.T.M., M.R.C.P.
Mayo Hospital, Calcutta

TUBERCULOSIS of the lungs in childhood is seldom reported in the medical literature in this country, but is not uncommon. The childhood type of tuberculosis, 'the primary complex of Ranke', is probably a comparatively rare occurrence, but the same cannot be said about the 'adult type' which is frequently met with in clinical practice. Many cases of the latter type are complicated with spontaneous pneumothorax. The case reported below is of peculiar interest inasmuch as a pleuro-peritoneal communication was established in a girl suffering from tuberculous pneumothorax.

Case report

A Hindu female school-going child, aged 9 years, was admitted into the hospital on 30th November, 1940, suffering from pain on the left side of chest, and dyspnoea for 3 days. She had also fever and cough. The present illness started with fever 6 weeks prior to admission. It was at first slight in the evening only—later remittent ranging up to 104°F. There was cough with expectoration for 25 days. She never had haemoptysis and there was no history of tuberculosis in the family.

General examination.—Thin, emaciated, orthopnoeic, slightly cyanosed, no oedema of the extremities, no enlargement of glands. On admission, temperature—98°F., pulse—130 and respiration—40 per minute.

Respiratory system.—No expectoration in hospital. Left side—bulging, restricted movement, hyper-resonant above and dull below, breath sound almost absent, metallic rales below. Right side—a few short rales in sub-apical region.

The heart was displaced to the right, its extreme end was in the fifth right inter-costal space just internal to the mid-clavicular line.

Abdomen.—The patient was doubled up. There was generalized rigidity over the abdomen; it was tender to touch; no mass was felt. The liver and spleen were not palpable. There was no vomiting; stools were passed daily.

Clinically she was diagnosed as a case of spontaneous tuberculous hydropneumothorax and possibly spontaneous pyopneumothorax with minimal involvement of right upper lobe. Peritonitis was also suspected.

X-ray examination on 3rd December confirmed the clinical diagnosis, both with regard to right and left lungs.

Blood examination on the 2nd: Haemoglobin—50 per cent, leucocytes—14,500 per c.m.m., polymorphonuclears—84 per cent, lymphocytes—10 per cent, monocytes—6 per cent.

Subsequent history.—On the 3rd, 400 c.cm. of air was withdrawn from the pneumothorax cavity (+ 12 + 4; — 400 c.cm.; — 2 — 12). She ran an intermittent temperature up to 101°F. By the 7th the lower part of the left side of her chest was oedematous, red and bulging. On the 8th an exploratory puncture brought out about 20 c.cm. of thick yellowish-white pus, which on staining did not show any acid-fast bacilli. Next day an attempt was made to draw out more pus. The pus was thick, and only a small amount came out in the syringe. Even on changing the level from the 7th to the 8th interspace, pus could not be aspirated. To reduce the positive pressure, another 400 c.cm. of air was taken out; pus flowed into the needle and interfered with the final reading. Her pulse was bad, and further attempt at aspiration was not made. She died 18 hours after.

Post-mortem report.—The right lung was emphysematous, and a small tuberculous focus was found at the apex. The left lung was tuberculous. There were about 10 ounces of pus in the left pleural cavity. The heart was normal. There were about 10 ounces of pus in the peritoneal cavity. The peritoneum was rough and showed signs of inflammatory reaction. There was a small tear in the oesophageal hiatus, through which the pus had probably travelled from the pleural to the peritoneal cavity. There was no sign of perforation in any part of the intestines, nor were there any signs of caseating glands bursting into the peritoneal cavity. On cutting open the whole of the intestines, a single circular ulcer was found in the terminal part of the ileum about one inch above the ileo-caecal junction, and a few small punched-out ulcers were scattered around the ileo-caecal junction. Pus from the peritoneal cavity and from the pleural cavity were both negative to acid-fast bacilli on Ziehl-Neelsen's staining. No animal inoculation of the pus was done.

Discussion.—Cases of spontaneous pneumothorax of tuberculous origin are found among Indian children. In some of them, there is

pyopneumothorax. The diaphragm being an effective barrier between the pleural and the peritoneal chambers, a pleuro-peritoneal pneumothorax is an extremely rare occurrence. An oesophago-pleural fistula in a case of tuberculous pyopneumothorax was however reported by Kanter and Madoff in 1937. Accidental pneumoperitoneum during artificial pneumothorax treatment was reported by Gaetan (1939) and Shrikhande (1940). But the author is not aware of any case being reported where the pus from the pleural chamber has burst into the peritoneal cavity. In this particular case pus was under tension, and found its way into the peritoneal cavity. Whether this had occurred prior to the admission of the patient into the hospital or whether it had occurred due to late aspiration of the fluid is debatable. On admission, the patient was doubled up and was complaining of pain in the abdomen wherever it was touched. The abdomen was rigid and peritonitis (from leakage of pus from the pyopneumothorax cavity) was considered a possibility. But the rigidity and tenderness persisted, or rather increased slightly, and a post-mortem examination was insisted on to make sure whether pus had entered the abdomen or not; and pus was found in the peritoneal cavity. Also it must be admitted that the level of the pus on the first day of exploratory puncture was distinctly at a higher level than that on the second day. It might be possible that there was a leakage of pus into the peritoneal cavity from the beginning and that, at a later date, the pus had rushed into the peritoneal cavity. This seems to be the possible explanation of the symptoms as they appeared. Another point of interest brought out by the post-mortem examination was the tuberculous ulceration of the ileum, which was never suspected clinically. This supports the view of many workers on tuberculosis that tuberculous ulceration of the intestines is more common than suspected.

Summary

1. A case is reported where the pus from a pyopneumothorax cavity has burst into the peritoneal cavity through the oesophageal hiatus.

2. Tuberculous ulceration was present in the terminal part of the ileum, when clinically it was never suspected.

Acknowledgment

My thanks are due to Dr. F. H. B. Norrie, the surgeon-superintendent, Mayo Hospital, for his kind permission to report this case.

THE NEED FOR A CHEAP AND EFFICIENT ANTI-MALARIAL DRUG IN INDIA

THE irony of the present unsatisfactory position of cinchona cultivation in this country is that it was India who made the first successful essay at cinchona planting. Java's earliest efforts were so unsuccessful that in 1864 they almost gave up the attempt, at a time when cinchona planting in India was beginning to attract the attention of private commercial enterprise, and in 1880 India and Ceylon were each producing a million pounds of bark against Java's half million. From this date up to the end of the century cinchona production in these countries increased by leaps and bounds (Ceylon produced 16,000,000 pounds of cinchona bark in 1887), a state of affairs which led to a severe slump and the inevitable crash in cinchona prices at the end of the century. From this crash the Java plantations survived, whereas in India and Ceylon the cinchona industry, as a commercial enterprise, died.

There were some obvious reasons for the survival of Java, such as a slight but distinct climatic advantage and the scientific control to which their planting had always been subjected, but whatever the cause it is quite obvious that had the government moved in the matter the industry in India could have been saved. As it is, Java has to-day a virtual world monopoly in cinchona products. India grows in her government plantations cinchona enough to produce 70,000 pounds of quinine a year, her average consumption amounts to about 200,000 pounds and her real requirements are about 1,000,000 pounds of cinchona alkaloid. In 1914, at the beginning of the last war, India was seriously alarmed at the prospect that she might find herself short of cinchona alkaloids, and, with the very real possibility that the war may spread in the Far East, the position to-day can scarcely be any less alarming.

We have again and again in these pages urged the adoption of some forward cinchona policy. But, whilst the medical (including public health) authorities have always agreed upon the necessity for some further action, they have never been sufficiently importunate to persuade the government to take this action, and in India we are once again faced with an urgent problem which is not susceptible to quick solution, for, even if cinchona cultivation were extended immediately, it would be ten years before any appreciable results would accrue, and the worst pessimists have not suggested that the war will last another ten years! It is now however a war-time problem for which we are

seeking solution, though it seems to have taken a war to revive interest in it.

There is to-day a very healthy revival of interest in the pharmaceutical industry in India. In order to show that the word *revival* is not ill-chosen, we will again quote two paragraphs that appeared in the first volume of the *Indian Medical Gazette* in 1866 :—

'We venture to indulge the hope that another septennial period will not pass away without our seeing the establishment of large chemical laboratories in each presidency—not mere repositories for the reception and distribution of imported drugs, or for the manufacture of a few tinctures, but pharmaceutical workshops on an extended scale, with highly qualified practical English Chemists attached to them—men who would analyse and test the products of the country; and make preparations, of what was valuable, in the most efficient way.'

Government might well initiate such a system, leaving it for completion, as they have done tea cultivation, to the enterprise of companies or of individuals.

With this general revival there is naturally an increasing interest being shown in the revival of cinchona cultivation. There are however two points of view, the commercial and the public health; these points of view are not incompatible, provided one does not completely dominate the other. Those who support the ultra-commercial point of view suggest that extensive cinchona planting should be undertaken with government encouragement, and if necessary support, so that eventually India will oust Java from the position of world monopolists. In other words, they would like to reproduce the state of affairs of the last slump, but, on this occasion, they will naturally demand, India must be saved by protection, or even subsidy.

This seems to us a wrong point of view. Our good friends, the Dutch in Java, have built up a splendid organization, and deserve the monopoly that they have acquired by science and industry. It should not be India's primary object to compete in world quinine markets, but, when there is evidence that she could supply the world's cinchona needs, it is absurd that she should not supply her own. But, if there is any extension of government cinchona planting, or if private enterprise is to be encouraged, the primary object, namely, the supplying of a cheap anti-malarial drug to the people, should be kept clearly in view and policy should be shaped to this end and to this end only. This again is no new policy for about the year 1874 when the government of Bengal replaced their low-quinine-yielding *Cinchona succirubra* by higher-quinine-yielding varieties, the Marquis of Salisbury, the Secretary of State for India at the time, emphatically condemned this policy. According to Wilson, *The Prospects of Cinchona Cultivation in India* (*vide infra*), his objection 'took the line that the object of introducing cinchona cultivation into India was not a commercial one but one having reference solely to the supply of a cheap febrifuge to the people of India. The question to be considered

was not what kind of bark fetched the highest price on the London market and was most sought after by quinine manufacturers but which kinds yielded the largest percentage of alkaloids which had been proved to be efficacious in the cure of fever'.

In 1928, the Royal Commission on Agriculture emphasized the importance of India's becoming self-supporting in the matter of her cinchona requirements and, in view of the emphasis that was laid on the urgency of this matter, it is surprising that 13 years later nothing material has been achieved. Again, in his Drugs Enquiry report of 1931 Sir Ramnath Chopra included the following recommendations :—

'The Cinchona Department should cultivate the species of cinchona best suited to the Indian climate, on a sufficiently large scale to make India self-supporting with regard to the alkaloids, and at prices commensurate with the economic condition of the Indian people.'

With a view to extending the cultivation of cinchona in India, experiments should be carried out in the growing of different varieties on a small scale in various areas, close connexion between the field and the laboratory being maintained'.

He also expressed the opinion that the 'factor which militates against the more extended use of quinine is its high price', and emphasized that the extensive adulteration and other dishonest practices associated with quinine were also due mainly to this high price. This report was issued nearly ten years ago and again what action has been taken on it, or on this particular aspect of it?

The argument may be put forward that cinchona cultivation is not the only aspect of the malaria-treatment problem and that there is the more difficult one of getting the drug to the people who need it. We do not close our eyes to this aspect of the problem, nor minimize its difficulties, but what we claim, and have repeatedly pointed out, is that the two problems are inextricably interwoven and are incapable of separate satisfactory solution. The main obstacle to the solution of the distribution problem is the high price of quinine, and the effect of this high price is a double-barrelled one; it naturally limits the amount of the alkaloid that the provincial governments can purchase for their hospitals and dispensaries, and it seriously complicates all attempts to distribute the drug free or at a reduced rate to the people. Quinine has a market value that is fixed by the monopolists in Java. This prevents the commercial sale of quinine by the quinine-growing provinces at a price lower than that of the market rate, except as a quixotic and foolish gesture that would benefit only the opportunist middleman, and, where free distribution is concerned, its high value places a serious temptation in the way of the many hands through which the quinine will naturally have to pass.

before it reached the ague-stricken peasant for whom it is intended.

It must be accepted therefore that the high price of quinine is a serious obstacle to progress. Can this price be lowered? The Bengal cinchona plantations and factories can produce quinine at about half the present world market price of this alkaloid, but the Indian plantations cannot in the present circumstances supply India's full requirements, so that the considerable balance has to be purchased from outside at world market prices. However, were we to extend our home cultivation, and there is evidence that this could be done, we could eventually become independent of outside sources of quinine and coincidentally of outside world prices, provided of course that we could prevent profiteering by exportation. This, however, would only get us over half our difficulty for the price would still be relatively high.

Could the price be lowered still further? Possibly the price of quinine could not: we do not know, but we do know that a preparation of mixed cinchona alkaloids could be produced at a very much lower price. In Manila Dr. Paul F. Russell reported that the Bureaux of Science, Forestry, and Prisons, in collaboration with the Rockefeller Foundation, have shown that an excellent preparation of mixed cinchona alkaloids of the totaquina standard could be prepared at a cost one-seventh that of quinine. If this could be done in India, and we have every reason to believe that it could, the problem of the treatment of malaria in this country would have travelled a very long way towards solution.

The first question that will naturally arise is, Is a mixture of cinchona alkaloids as good as quinine as an anti-malarial drug? The answer is that any mixture of cinchona alkaloids is not necessarily as good as quinine, but that one satisfying the 'totaquina' standards is as good, or very nearly as good, as quinine. The most unfavourable interpretation that has been given to the term *very nearly* is ninety-five per cent; usually the relative value of totaquina as an anti-malarial drug as compared with quinine is placed at a higher level than this, and there are many who believe that the mixed alkaloids are more efficacious than quinine in certain forms of malaria.

The totaquina standard was originated by the Malaria Commission of the Health Organization of the League of Nations as being an efficient anti-malarial drug that could be prepared from the hardier cinchona plants in the form of a preparation of crystallisable alkaloids mixed in the proportion in which they occur in the plant. This standard was universally accepted, it appeared in the *British Pharmacopœia* 1933, and subsequently in many other national pharmacopœias. At the suggestion of this Commission trials with this preparation were carried out in a number of countries, in

India, Malaya, Roumania, Algeria, Formosa, China, and the Philippines, and in every instance its efficacy has been confirmed.

A question that will naturally arise in the mind of the critical observer is, If the mixed cinchona alkaloids are so satisfactory, why, after using mixed alkaloidal preparations for many generations, did the medical profession turn away from them and express a preference for the pure alkaloid quinine? That they did give the lead in this matter is obvious. The explanation is not difficult and does not entail any indictment of our predecessors. When the chemist separated and identified the various alkaloids in cinchona bark, the scientific mind of the medical profession naturally wished to know which of the many alkaloids that it contained was the most efficacious; investigation showed that, on the whole, quinine was the most effective alkaloid in the treatment of malaria, so that quinine became the alkaloid of choice and therefore the most valuable one; consequently the grower and the manufacturer took up their cue and aimed at growing only the high-quinine-yielding varieties and manufacturing only quinine. The former tendency was all to the good, provided it did not entail the limitation of planting areas; the latter was not so beneficial for it meant that the other alkaloids for which there was little demand were virtually wasted and the price of quinine had to be raised to compensate for this loss. One measure that the manufacturers adopted to avoid this loss had an even more unfortunate repercussion; having removed the more valuable alkaloids, including the quinine, they marketed the balance of mixed alkaloids as cinchona febrifuge. Not all cinchona febrifuges were bad, but many contained little more than the almost inactive amorphous alkaloids and were practically useless in the treatment of malaria. The natural result was that the medical profession turned more firmly towards the pure alkaloid quinine whose action could be relied upon every time, and cinchona febrifuge acquired a very bad name, which it has not yet been able to live down. The standardized product, totaquina, is an entirely different proposition; it has not had its valuable alkaloids removed, and it does not contain more than a minimum of the viscous amorphous alkaloids that tend to make the tablets hard and insoluble. The *British Pharmacopœia* standard for totaquina demands that it shall contain at least 70 per cent of crystallisable alkaloids of which at least 15 per cent shall be quinine, and that it shall not contain more than 20 per cent of amorphous alkaloids, 5 per cent of water, and 5 per cent of ash and mineral matter. An alkaloidal mixture of this standard can be made from the total alkaloids of the hardier and hybrid species of cinchona without the separation of the individual crystallisable alkaloids or the addition of extra quinine; thus, not only is the usable alkaloidal output very much greater than it

would be if only quinine were separated, but the process of manufacture is simplified.

Two criticisms have been raised, and by people in responsible positions who should have known that their objections were frivolous; the first is that proper standardization of total alkaloid mixtures would necessitate the prior separation and purification of the individual alkaloids and subsequent mixing, so that the cost of manufacture would be unaffected, and the second is that, once the value of the other crystallisable alkaloids is appreciated, their price will automatically rise to that of quinine. The latter argument we can dismiss as being the ultra-commercial point of view, and not very sound at that. The degree of standardization that is envisaged in the first criticism is entirely unnecessary; the wide margin allowed in the preparation of *British Pharmacopœia* totaquina was designed to obviate such accurate and expensive standardization, and the raising of this objection seems to us to be an attempt to perpetuate a mistake that has already been made. We remarked above that we could explain the apparent reversal of medical policy during the last seventy-five years without criticizing our predecessors; we might perhaps qualify this by adding 'on scientific grounds', for we must criticize them on the grounds that they failed to face realities; they created the pure-quinine cult without realizing where it would lead to. They perhaps could not have foreseen this, but for very many years it has been only too apparent and they should have been ready to call a halt. For generations—for a century or more—powdered cinchona bark was used as an anti-malarial drug and proved a very efficient one; we are not suggesting that we should have been satisfied with this and not have tried to find something better, but wasn't it going a little too far to insist, and to teach generations of doctors and eventually the public, that only this one alkaloid, quinine, was of any real value in the treatment of malaria, and thereby to raise its price out of the reach of the peasant and to such a level that government dispensary budgets could not afford to purchase for distribution to their patients more than a tithe of the amount that is really required. We are not suggesting that we should go back to powdered bark—though this would be better than the quinine-less 'quinine mixtures' that are sometimes dispensed—but that as we now have a preparation of mixed alkaloids that, in the opinion of many, is as good as and often better than quinine, we should prescribe it whenever possible, and that in government hospitals and dispensaries quinine should be given only in the very exceptional cases where this specific alkaloid is indicated.

We said above that no material action had been taken on the recommendations of the Royal Commission on Agriculture; this is, we believe, true, but in 1937 on the recommendation of the Indian Research Fund Association

through the Central Advisory Board of Health and with the approval of the Governing Body of the Imperial Council of Agricultural Research, the Government of India appointed an officer 'to determine what areas in India are most suited to cinchona cultivation and what would be the cost of production in such areas'. The terms of reference of this inquiry do not seem to be particularly explicit and the fact that the primary object of the recommendation was a medical one seems to have been lost sight of in its passage through the various bodies; there is at any rate no evidence that Mr. Wilson, who undertook this enquiry, ever consulted malarialogists, or any other medical authorities, before commencing his investigations or making his recommendations on a subject which, as we have said, is basically a medical one. The incident seems to have been a particularly bad example of water-tight departmentalism; an invaluable opportunity has been missed of constituting a combined medical, chemical and agricultural committee. As it is, the report that has been produced, though an extremely interesting one and no doubt very valuable from an agricultural point of view, has taken us not a yard nearer the solution of the vital problem of providing a cheap anti-malarial drug for the people of India, because the writer had no idea what the real medical and public health requirements were, made no attempt to find this out, and in fact viewed the whole matter entirely from the commercial point of view. In support of this criticism we need only quote a paragraph that appears at the very beginning of the report proper, after the historical survey:

'In this investigation it is the land considered suitable for *Cinchona ledgeriana*, that has been selected. *Cinchona ledgeriana*, when properly cultivated, yields the most profitable return because it contains the maximum quantities of quinine. To recommend any other variety in preference would go against the verdict of history.'

The commercial spirit that is reflected in this paragraph and the false premise—which he appears to have made no attempt to check—that the medical profession is only interested in the alkaloid quinine, have steered his enquiry into sterile channels, sterile as far as the malaria treatment problem in India is concerned. The last paragraph of his summary and recommendations, if it has any meaning at all, is in no sense a conclusion but merely a reiteration of this premise, for it appears to have no direct reference to anything contained in the report:—

'In the meantime, pending the arrival of more workers in the cinchona field, it would be correct to say that the interest for India lies in the hope of plentiful supplies of quinine rather than the prospect of increasing supplies at mass production rates.'

Mr. Wilson refers to the verdict of history. May we remind him that the adoption of an ultra-commercial policy, in which the needs of the people take second place, has already called forth a rebuke from a famous Secretary of State? It is not beyond the bounds of possi-

bility that future historians may record how those who pursued this policy received a similar rebuke from a famous Viceroy.

There are two ways in which the governments in India could set about this problem; they could extend their present plantations, still growing the high-quinine-yielding *Cinchona ledgeriana* in areas suitable for its cultivation, but not limiting their planting to such areas and growing hardier species, such as *Cinchona robusta*, in other areas unsuited to *ledgeriana* cultivation, and in their factories manufacture a large preponderance of totaquina and smaller amounts of pure alkaloids; and/or they could encourage private enterprise in cinchona cultivation, and possibly in cinchona alkaloid manufacture.

It has been suggested that the governments should subsidize concerns prepared to grow cinchona; this, we consider, should be entirely unnecessary, for the capital outlay is not great and, if the price of bark is maintained, it should be a very profitable industry. It will be noted that there is an 'if' here, and this is where the government could assist. We are informed from a reliable source that if the government would guarantee a price for bark, not less than half the present price, cinchona planting would provide a profitable return. We cannot claim to have any expert knowledge in such matters, but surely, if the government can exercise any effective control over fully-grown industries, such as tea and jute, they could control the growth of what would be virtually a new industry.

A suggestion was recently made by a small neighbouring State which has a great deal of land suitable for cinchona cultivation, that they should introduce cinchona cultivation as a cottage industry; as it would be nearly ten years before they could expect any return for the outlay and work, the State authorities naturally did not wish to encourage their subjects to undertake this, unless an adequate price for the bark could be guaranteed. This is surely the type of enterprise that deserves encouragement. The cottage industry suggestion might well be adopted in provinces in British India, such as Assam.

Our readers may say what has all this to do with us? How can we influence government policy? Even if we put aside the fact that, in a country governed on democratic principles, every voice that is raised helps to influence the government, there are more direct ways. The demand for pure quinine, which has indirectly been the cause of so much trouble, originated with the medical profession, and it is from them that the demand for the standardized mixture of the alkaloids (or totaquina) must come. We have repeatedly pointed this out, and there is evidence that the teaching of those who share with us this point of view has borne fruit and that the

demand for cinchona febrifuge is outstripping production, for a circular was recently issued by the Bengal Government limiting the amount of cinchona febrifuge that can be ordered for dispensaries and hospitals to fifty per cent of the total anti-malarial drugs, the balance being made up of quinine. This, we sincerely hope, is only a temporary measure to meet the present situation, for it would be a tragedy (not to say

a crime) if it indicated that the finance departments were demanding that hospitals and dispensaries with their limited budgets should purchase the more expensive drug, in order that the government could swell their profits.

We feel very strongly that no real progress will be made in this matter until the commercial is made subservient to the medical point of view.

(16) The red cell fragility test

Introduction.—When normal red cells are suspended in 0.85 per cent saline they remain unaltered, but they become crenated when the concentration of the saline is raised above 0.9, whereas they are haemolysed, or 'laked', when the concentration is lowered below 0.45 per cent.

The study of the reaction of the red cells in hypotonic saline solution is known as the fragility test of the red cells. The test can be done by either a qualitative or a quantitative method; it is conveniently done with fresh oxalated venous blood collected for routine examination of the blood (part I), but it can also be done with ordinary (non-oxalated) venous blood, or with the capillary blood from the finger.

The fragility of the red cells is expressed in terms of percentages of sodium chloride solution, namely, the points at which haemolysis commences and at which it is complete.

Qualitative method

To each of a series of numbered test-tubes containing saline solution of different graded concentrations, one drop, or two drops of blood are added; the contents of the tubes is mixed

(iii) Metal rack for holding the tubes.

(iv) 5 or 10 c.c.m. syringe with needle of fairly wide bore.

A convenient form of rack is that used for the Wassermann reaction. The holes are in two rows, with single tubes at either end of the rack. The holes are numbered 12 to 24 and those at each end 'S' and 'W' (figure 1).

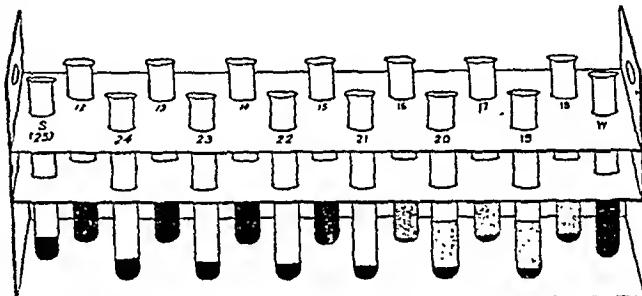

Fig. 1.

Technique

With a syringe fitted with a needle of fairly large bore, put into each tube the number of drops of 0.5 per cent sodium chloride solution indicated by the number on the rack opposite that tube, and 25 drops in the tube marked S.

Wash out the syringe thoroughly with distilled water. With the same needle, add a sufficient number of drops of distilled water to bring the total number of drops of fluid in each tube up to 25, and 25 drops of distilled water in the tube at the end of the rack marked W.

Example.—

Numbers on racks opposite test-tubes

Number of drops of 0.5 per cent NaCl to be put into
each test-tube

Number of drops of distilled water to be added to
each test-tube

	W	12	13	14	15	16	17	:	:	:	24	S
	0	12	13	14	15	16	17	:	:	:	24	25

well and allowed to stand for about 2 hours, after which the numbers of the two tubes that show the beginning of haemolysis and complete haemolysis are noted, and from these the strengths of the corresponding saline solutions are calculated.

Apparatus and reagents required

- (i) Accurate solutions of sodium chloride, 0.5 per cent and 1.0 per cent, standardized against silver nitrate solution.
- (ii) Small test-tubes.

Shake each tube thoroughly to get a uniform mixture. To each tube add one drop, or two drops if the patient is very anaemic, of blood with a syringe, either directly from the patient or from the oxalated blood in the flask. (If great accuracy is aimed at, the test should be performed with washed red cells, as the red cell is protected from saline haemolysis by its own plasma.)

Shake all the tubes again. Place the rack with the tubes on a flat even surface and allow

it to stand for about 2 hours at room temperature. If there is any special need for hurry, centrifuge all the tubes for about 10 minutes and take the readings at once. If possible, put up a parallel test with normal blood as a check to the accuracy of the sodium chloride solution.

Reading the results.—Hold the rack with the tubes level with your eyes against daylight. Note the number of the tube in which haemolysis is first shown and also the number of the tube in which it is quite complete. Examine the tubes commencing from tube no. 25 and proceed towards the other end; the first tube showing a tinge of reddish colour in the supernatant fluid indicates the beginning of haemolysis and the first tube in which all the corpuscles are laked and no corpuscular residue is visible, even after centrifugation, indicates the point of complete haemolysis.

The result is expressed as percentage of sodium chloride solution and is calculated by multiplying the figures on the tubes by 0.02.

Example.—

The first tube in which the supernatant fluid shows any pink colour is numbered 20.

The first tube in which there is no corpuscular residue is numbered 15.

Therefore, haemolysis begins at $20 \times 0.02 = 0.40$ per cent saline.

Haemolysis is complete at $15 \times 0.02 = 0.30$ per cent saline.

When the test has to be carried out with very fragile cells, e.g., in acholuric jaundice, concentration of sodium chloride of over 0.5 per cent may be required; in such a case use one per cent solution instead of 0.5 per cent and proceed with the test in the same way as before. Take the readings, and multiply the numbers on the tubes by 0.04 to get the percentage of the saline.

Normally, partial haemolysis begins at about 0.44 per cent, and is complete at about 0.30 per cent saline.

Quantitative method

The 'qualitative' method would be quite accurate if all the cells in any particular sample were of the same fragility, but the individual cells vary in their fragility just as they vary in their size. It is therefore important to know what percentage of cells have been haemolysed by each solution. This quantitative method is more laborious, but is worth doing in special cases:

Principle.—A number of accurate red cell counts are done in the usual way except that instead of the standard diluting fluid different strengths of salt solutions* are used; from the results an accurate quantitative graph of the fragility is plotted.

Apparatus required

As in red cell count (part II).

Also, accurate solution of sodium chloride (standardized against silver nitrate solution) from 0.3 to 0.7 per cent with intervals of 0.05 per cent.

Technique.—Fill red cell pipettes as in the red cell count using different strengths of salt solution ranging from 0.3 to 0.7 per cent with intervals of 0.05 per cent. Allow the pipette to stand on an even surface for about 15 minutes, shake it well, and then count the red cells in the usual way (see enumeration of red cell, part II).

Repeat this count with each solution and include a control with the usual diluent.

From the above counts calculate the number of cells that become haemolysed in different strengths of the salt solution and plot a curve. The normal limit of fragility of the red blood cells, as determined by the quantitative method of Whitby and Hynes (1935), is shown in figure 2.

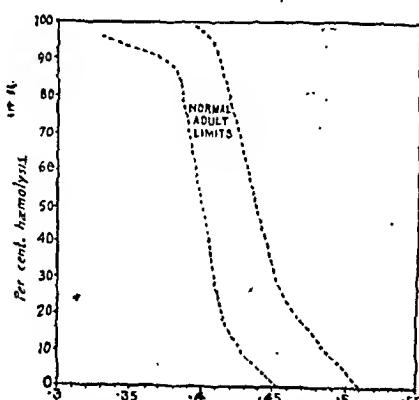

Fig. 2.—Fragility of red corpuscles as determined by quantitative method (Whitby and Hynes, 1935).

Discussion

The fragility test is based on the assumption that there is some parallelism between the fragility of the erythrocytes *in vitro* and their susceptibility to haemolysis *in vivo*. Though it is very unlikely that the mechanisms of these two processes, neither of which is fully understood, are identical, there is the evidence that in certain conditions, e.g., acholuric jaundice, where the red cells are particularly liable to haemolysis *in vivo*, they are haemolysed by hypotonic saline solutions that would not affect normal erythrocytes.

In the physiological process of red cell demolition, there is some evidence that the red cell, normally a biconcave disc, becomes more spherical in shape before it disintegrates, and in many 'haemolytic' anaemias it has been shown that the red cells are more spherical than the normal red cell. These spherical cells appear to be more susceptible to haemolysis by hypotonic salt solutions, but it is certain that this is not the only change that brings about this increased fragility.

In all cases of obscure anaemia it is certainly worth carrying out the fragility test, by the quantitative method if this is feasible, not only

* Simmel (1923) used mixtures of salts identical with those in the blood, but Whitby and Hynes (1935) obtained identical results by using sodium chloride solutions; we recommend the latter method on account of its simplicity.

in the interests of accurate diagnosis but in order to add to our knowledge of the aetiology of the many types of anaemia about which our knowledge is incomplete.

(17) *Procedures employed in investigating haemorrhagic diseases*

Introduction.—In the study of haemorrhagic diseases and haemorrhagic diatheses, a number of procedures are commonly carried out that should be included in this series on haematological technique. These are :—

- A. Estimation of the coagulation time.
- B. Estimation of the bleeding time.
- C. Quantitative estimation of prothrombin in the blood, or determination of prothrombin time.
- D. Capillary resistance test.
- E. Study of clot retraction.
- F. Platelet count (*vide part III*).

The study of clot retraction gives little additional information of value, as it appears to be dependent entirely on the platelet count, but, as it provides confirmatory evidence, we have included it. The estimation of blood calcium also has some bearing on this subject, but is essentially a biochemical test and will not be described here; further, though calcium deficiency could theoretically lead to a haemorrhagic state, in actual practice it does not appear to do so, unless associated with other deficiencies.

Discussion.—Briefly stated, and essentially, coagulation of the blood is dependent on fibrinogen, ionized calcium, prothrombin and thrombokinase (thromboplastin). The first three are present in the plasma, while thrombokinase is derived from the disintegration of the platelets and damaged tissue; the chain of events is as follows :—

Prothrombin + ionized calcium + thrombokinase (thromboplastin) \rightarrow thrombin.

Thrombin + fibrinogen \rightarrow fibrin.

Fibrin + cellular elements of blood \rightarrow blood clot.

Clot + platelets \rightarrow the retracted clot.

(This leaves out of account the interaction between anti-prothrombin, prothrombin, and thromboplastin substances. Heparin—anti-prothrombin—is a very real substance, but whether it exists in the circulating blood in health does not seem definitely established, so, for the sake of brevity and, we hope, clarity, we have not considered the part it may possibly play in preventing clotting in the circulating blood.)

All the above substances are normally present in the blood and a defect in any of them will cause a break in the continuity of the chain, and will lead to haemorrhage.

Known causes of the haemorrhagic state are :—

- (i) Deficiency of platelets (and consequent deficiency of thrombokinase), as in thrombocytopenic purpura.
- (ii) A defect of the platelets so that they do not disintegrate at the usual rate, as in haemophilia.
- (iii) A deficiency of prothrombin in the blood, as in vitamin-K deficiency.

- (iv) Fibrinogen deficiency, as in prolonged chronic haemorrhage.
- (v) A defect in the capillary walls, as in vitamin-C deficiency.
- In (i) there is a decrease in the platelet count, a normal coagulation, but a prolonged bleeding time, and poor clot retraction; the prothrombin is normal.
- In (ii) the bleeding time is normal and the coagulation time is prolonged.
- In (iii) the bleeding time is normal and coagulation time prolonged; prothrombin is decreased, but the clot retracts normally.
- In (iv) the bleeding time is normal and coagulation time prolonged; and the clot retraction is defective, but prothrombin is normal.
- In (v) the bleeding time is prolonged and the 'capillary resistance' is decreased, but the coagulation time, prothrombin and clot retraction are normal.

A. Coagulation time

Various methods have been described for the determination of the coagulation time, but it is essential to adopt one method and to follow the technique as uniformly as possible, for the normal coagulation time varies very considerably with the technique, with the temperature, and with the diameter of the tube used; it is also influenced by admixture of the blood with tissue juice or any other foreign substances. It is advisable first to determine the coagulation time of a few normal persons in each laboratory; all subsequent examinations must be done exactly in the same way and the results interpreted in relation to the normal findings.

Two methods are described, as we have had considerable experience with each.

I. Capillary tube (Wright's) method

Apparatus and reagents required

- (i) Fine capillary tubes, with diameters from 0.8 to 1.2 mm. and six inches long.
- (ii) Pricking needle or blood gun.
- (iii) Water-bath, or warm water in a beaker at 30°C., with a thermometer.
- (iv) Spirit lamp.
- (v) Stop watch.
- (vi) Alcohol.
- (vii) Ether.
- (viii) Cotton-wool.

Technique.—Clean a finger or an ear lobe, first with alcohol and then with ether. Puncture sharply and fairly deeply with a blood gun or a pricking needle, so that blood will flow freely without the necessity of squeezing. Discard the first two drops of blood, and then fill a capillary tube up to three-fourths of its total length with blood (the capillary tube will fill by capillary attraction when held against the drop of blood). Note the time by the stop watch when the blood first enters the capillary tube. Seal the free ends of the tube in a flame and put it in warm water (37°C.) in a beaker. Repeat the process with two other tubes, noting the time of the commencement in each case.

After one minute, take out the first tube, gently break off a portion of the tube from one end, and repeat this every 15 seconds until a thin line of unbroken coagulum is seen stretched between the two broken ends; note the time. The difference between the two times by the stop watch is the coagulation time. Repeat the procedure with the other two tubes, breaking them at intervals of 15 seconds, and find out the coagulation time for each tube.

Take the mean of the three readings as the coagulation time.

Normal time limits = 1 to 3 minutes.

II. Method of Lee and White (modified); with venous blood

Apparatus and reagents required (additional)

- (i) An all-glass 5 c.cm. syringe, with a needle of fairly large bore.
- (ii) Small test-tubes $\frac{1}{4}$ inch in diameter with rubber corks, in a rack.
- (iii) Normal saline.
- (iv) Hard paraffin in a metal or porcelain bowl.

Prepare a water-bath at 37°C. and the paraffin tubes; place the paraffined tubes ready in the bath in an upright position.

Collect 5 c.cm. of blood from a vein in an all-glass syringe immediately after washing it out with normal saline. Note the time by the stop watch when the blood enters the syringe.

Take out the needle from the syringe, and put exactly 1 c.cm. of blood into each of the three tubes. Cork the tubes with rubber corks and allow them to stand in the water-bath. Wait for 3 minutes, and then every 15 seconds in rotation take a tube and tilt the contents to see if the blood has set. Continue doing this until the blood is found to have set, so that the tube can be inverted without spilling any blood; note the time.

Normal time limits = 3 to 6 minutes.

Comment.—The second method is more accurate, as certain disturbing factors, e.g., tissue juice, are eliminated.

B. Bleeding time

I. Duke's method

Apparatus required

- (i) Pricking needle or blood gun.
- (ii) Filter-paper.
- (iii) Stop watch.
- (iv) Sphygmomanometer.

Clean the ear lobe or the dorsal surface of a finger, first with alcohol and then with ether. (The tip of the finger is not suitable for this test as it is horny in many cases.) Prick the selected site fairly deeply with a blood gun or a pricking needle, so that blood flows freely without squeezing. Soak up the blood which comes out with a clean piece of filter-paper without touching the skin. The flow of the blood should be such that the first impression on the filter-paper has a diameter of about half an inch. Continue to soak up the blood with the filter-paper every 30 seconds until the bleeding stops.

The time from the first appearance of the blood until the cessation of bleeding is the bleeding time.

Normal limits = 1 to 3 minutes.

II. Venous pressure method (Ivy et al., 1935)

Put the cuff of a sphygmomanometer around the arm above the elbow as is done in taking blood pressure. Select a portion of the forearm below the elbow and clean it with alcohol and ether. Raise the pressure and maintain it at 40 mm. of mercury, which is sufficient to check any venous return. Prick sharply up to a depth of about 1/10th inch, at a point free from any superficial veins, so that blood will flow freely. Soak up the drop of blood every 30 seconds, as in method I, until the bleeding stops.

This method is superior to method I, as the capillaries are kept wide open and their tone eliminated; also the area selected for puncture is uniformly thin. For these reasons more consistent results are obtained with this method than with method I.

Normal limits = 2 to 4 minutes.

C. Quantitative determination of prothrombin in blood; prothrombin time

Apparatus required

- (i) Ten c.cm. record syringe.
- (ii) Centrifuge tubes.
- (iii) Small test-tubes in a rack.
- (iv) Water-bath with a thermometer.
- (v) Capillary pipettes with teats.
- (vi) Stop watch.

Solutions required

- (i) Sodium oxalate solution: dissolve 1.34 grammes of chemically-pure anhydrous sodium oxalate in 100 c.cm. of distilled water.
- (ii) Calcium chloride solution: dissolve 1.11 grammes of chemically-pure anhydrous calcium chloride in 100 c.cm. of distilled water. Check the strength of the solution by titration against silver nitrate solution.
- (iii) Thromboplastin solution.

Preparation of thromboplastin solution

Satisfactory results will be obtained with either of the following substances:

(a) From rabbit's brain: Dissolve 0.3 grammes of dehydrated* rabbit's brain in 5 c.cm. of normal saline containing 0.1 c.cm. of sodium oxalate solution, incubate at 45°C. for 10 minutes and finally centrifuge at a low speed for 5 minutes. Pipette off the milky supernatant fluid and keep the solution in a cold incubator, floating a little toluene on the top of the solution. The solution will keep for about a month.

(b) From Russell's viper venom.

A 1 in 20,000 solution of Russell's viper venom gives a potent thromboplastic solution. In the dried state the venom maintains its full potency indefinitely; Mr. N. K. Iyengar informs us that, kept in a refrigerator with toluene, the solution also retains full potency for more than a month.

* Dehydrating the brain: Remove all the blood vessels, and then macerate well in a glass mortar. Add acetone and macerate again. Decant off the acetone, add some fresh acetone, macerate, and again decant off the excess of acetone. Continue doing this until the whole thing is converted into granular powder; keep in a cold incubator. In the dried state its activity is retained for a long time.

Technique.—A slightly modified Quick's method is followed:—

Put 0.5 c.cm. of sodium oxalate solution into a centrifuge tube.

Collect blood in a dry syringe (*vide* part I) and put 4.5 c.cm. into the centrifuge tube containing oxalate solution; mix well.

Centrifuge until the plasma completely separates; carefully pipette off the supernatant plasma and put it into another dry sterilized tube. Put exactly 0.2 c.cm. of plasma into each of the three tubes marked A, B, and C.

Keep the water-bath ready at 37°C. Take three of the dry test-tubes and to each add exactly 0.2 c.cm. of thromboplastin solution and 0.2 c.cm. of calcium chloride solution.

Put one tube containing the plasma into the water-bath, and, when it is warm, to it add the mixture of thromboplastin solution and calcium chloride solution, from one tube; note the time when the mixture is added to the plasma; shake gently keeping the tubes in the water-bath, and again note the time when the clot first appears.

Repeat the experiments with the other two tubes. Take the means of the three headings; this gives the prothrombin time.

Normal = 15 to 25 seconds.

D. Hess' capillary resistance test

Apparatus required

- (i) Sphygmomanometer.
- (ii) Stethoscope.
- (iii) Hand lens.
- (iv) Skin marking pencil.

Place the cuff of a sphygmomanometer on the arm above the elbow as in taking the blood pressure.

Determine the systolic and diastolic pressures; release the pressure. With a skin (or glass) pencil mark any purpuric spots that may be present on the forearm.

Raise the pressure to a point midway between the systolic and the diastolic, and maintain it at this point for 5 minutes. Remove the armlet and examine the forearm in a strong light, and if necessary with a hand lens, for purpuric spots (other than those already marked). A positive result, indicating decreased capillary resistance, is shown by the presence of a number of small fresh purpuric spots distributed over the forearm below the point at which the armlet was applied.

The process should be repeated on the other arm.

E. Clot retraction study

When blood coagulates, a clot is formed which after a time contracts and expresses the serum; the clot itself then shrinks and becomes hard. Retraction of the clot, as it is called, varies directly with the number of platelets in the circulation, but is independent of the coagulation time; with a low platelet count, 60,000 per e.mm.

(Continued at foot of next column)

WATER IN RELATION TO HEALTH*

By RAO SAHIB T. N. S. RAGHAVACHARI

The King Institute, Guindy

PUBLIC health has been defined as the science and art of preventing disease, prolonging life and promoting physical health and efficiency

* An address delivered before the Society of Biological Chemists, India, at the University Biochemical Laboratory, Madras, on 5th May, 1940.

(Continued from previous column)

or below, it takes over 24 hours for the clot to separate and the clot is soft and friable.

Apparatus required

- (i) Same as for collecting blood.
- (ii) Graduated 10 c.cm. centrifuge tubes, each fitted with a cork having a hole in the centre.
- (iii) Glass rods with flanges, about the size of a silver 4-anna piece half an inch from the end.
- (iv) Test-tube rack.

Method of Macfarlane.—Collect blood from the patient in a dry syringe (*vide* part I).

Put 5 c.cm. of blood into the centrifuge tube. Put in the cork with the glass rod passed through the hole in the centre of the cork. See that the flanged end of the rod is near the bottom of the centrifuge tube (figure 3).

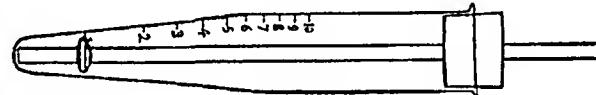

Fig. 3.—Showing centrifuge tube with glass rod in position.

Place the tube in an upright position in the rack and put the rack into an incubator at 37°C.

From one hour onwards, examine the tube from time to time for clotting.

After one hour of clotting, remove the clot by drawing out the glass rod (the clot will adhere to the flanged end of the rod).

Note the amount of fluid in the tube.

The amount of fluid in the tube divided by the amount of blood put in the tube and multiplied by 100 gives the percentage of retraction.

Example.—

Suppose 5 c.cm. of blood was taken and 3 c.cm. of fluid was left after the removal of the clot.

Retraction = $\frac{5 - 3}{5} \times 100 = 60$ per cent.

Normal retraction = 48 to 64 per cent.

The clot is also examined for firmness and friability.

Clot retraction is low in thrombocytopenic purpura, but is normal in haemophilia.

through organized effort. Modern public health had its origin in England in the middle of the nineteenth century when sanitary conditions had become intolerable in cities as a result of industrial development. Public health first concerned itself with the improvement of the environment and was really, therefore, an art at that time, as the biologist, the chemist and the biochemist had not given to the world the scientific principles upon which modern public health is based. Municipal sanitation was the main theme of any public health programme. Although the germ theory of disease had not been established, it was recognized that an abundance of good water was necessary to promote health in urban areas, and it was also known that the spent water required to be transported to a safe distance in order to prevent unbearable conditions.

With the advent of the bacteriologist, in the latter half of the last century, preventive medicine became a prominent feature of environmental sanitation. To-day, the physiologist and the biochemist have given a fresh impetus to the movement of health conservation; and personal hygiene, collectively applied, forms part of a well-organized public-health programme. The provision of protected water supplies, of efficient sewage disposal, of suitable legal and other enactments for ensuring safe supplies of milk and foods and of various amenities that make for comfort and good health, looms large in the horizon of the modern public-health atmosphere.

Even in this country of ours, there has been of recent years an awakening to the necessity for and the beneficial effects that would accrue from a well-ordered control of water and milk supplies, sewerage, housing and nuisances, and the bulk of the activities of the public health and sanitary engineering departments in this province has centred round these problems. I must, however, say that we have but just entered the outermost fringe of modern public health as judged by western standards. The relationship of water to health is my theme for to-night and it sounds such an absurdly simple one that one may be tempted to ask what is the wonderfully new thing that I am going to tell you, which you do not know already. Let me at once say it is indeed a simple matter and at the same time, it consists of a variety of important and intricate facts, some of which, at any rate, would be interesting to many of you.

It is perhaps unnecessary for me to tell you that pure water does not exist in nature and that the common impurities exist either in solution—gases, minerals or salts, organic matter—or in suspension—silt, sand, clay, and living organisms as algae and bacteria. Some of the impurities are of no consequence except when present in large amounts, while others are of such great and grave importance (these include the disease-producing bacteria) that they must be removed or kept out of the water by taking

all possible precautions. A *safe water* is one that will not cause disease or other injury to persons who drink it. A *potable water* is one that is suitable for domestic use and, therefore, safe to drink, in addition to being usable for cooking, washing, bathing and watering cattle. A *polluted water* contains organic matter or wastes to an extent which renders it unfit for domestic use. A *contaminated water* contains germs that would cause disease. The common water-borne diseases, as you know, are typhoid, dysentery—both bacillary and amoebic—and cholera. I do not propose to tell you about the mode of spread of these diseases through water. The presence of organic impurities in excess—derived from animal and vegetable sources—apart from the presence of incidental bacterial contamination, can, *per se*, account, at best, for vague gastric upsets, particularly in delicate individuals and in persons who are psychologically conscious. The presence of algae in considerable amounts has been incriminated in the production of gastric disorders, e.g., diarrhoeas, and has also been considered to be deleterious to cattle in certain cases, where the water level of ponds had gone very low, resulting in a rich concentration of algal life. There has, however, been no authentic record of specific instances where this aspect of the problem has been proved on the basis of a mathematical equation. And I must frankly tell you that such convincing proofs are difficult to adduce in view of the many other factors that go to make up the story.

Now, these ubiquitous forms of life known as algae occur in all surface waters and show seasonal variations in preponderance and productivity. They have been studied from various aspects by several eminent biologists all over the world. Dr. Mortimer of the Freshwater Biological Association at Wray Castle, in a recent contribution, laid great emphasis on the role of the 'nitrogen balance' in water and of phosphates in algal productivity.

The findings of western observers in respect of many problems are often accepted by us here, as though they were universally applicable under all conditions. No doubt, in many cases, their findings would have been based on laborious research extending over several years and covering a variety of conditions and materials. But, are they all, therefore, universally applicable to every country and every type of climate? The answer to this question can be furnished only by the same process which was responsible for the original findings, viz., research.

The mention of the word, *research*, is, sometimes, enough to scare many people and there have been several occasions when I have heard responsible civic administrators say, 'No more research on our water supply, please; there has been enough already of that sort of thing'. These well-meaning but ill-informed people think that research on a particular subject shall

be done once and for all and the findings reached are immutable for all time. Research is not something elusive and fantastic to be used only within the mystic atmosphere of a laboratory. It is an organized and diligent investigation to discover facts which may be applied with equal facility and assurance to the solution of any problem in any realm of human activity. It is a tangible, ever-ready tool, the wise use of which begets results whose value exceeds the expenditures in time, effort and money. To a large extent, research is an attitude of mind, that attitude which prompts one to be asking eternally the question *Why?* that attitude which does not permit the closing of the mind, that attitude which leads to ascertaining what people in other countries and in other walks of life are doing, and adapting only that which is adaptable to one's own work and rejecting what is not applicable, that attitude which warns against the folly of complacency and satisfaction with things as they are, that attitude which expresses itself pithily but eloquently in the short phrases, 'What is not yet, may be', and 'What may be, should be shown to be'.

Each phase of knowledge is connected by strings, often invisible, to a previous state of knowledge. This connection has to be explored, discovered and carefully examined for its suitability of application to the conditions obtaining in each locality. As instances I may mention :

(i) the behaviour and reactions of certain *coliform* bacteria found in the tropics, to certain tests which are considered specific in the temperate regions, have been shown, by carefully controlled research conducted by me at the King Institute, during the past three years, to be different to those recorded in England.

(ii) the classical work of the late Sir Alexander Houston of the London Metropolitan Water Board, on storage as a great safety factor in water purification, legislated for three months' storage of river and upland surface waters for ensuring perfect safety. Work carried out at the King Institute with a river water in 1930 showed that storage for more than 5 days was not helpful under tropical conditions, as there was a tendency to bacterial increase after the fifth day and a liability thenceforth to excessive algal growths.

(iii) Again, certain factors that are credited with the power to influence the productivity and predominance of algal forms in a profound manner in English reservoirs and lakes do not appear, from our recent researches (still in progress at the Institute) to be applicable to tropical conditions. Thus, the majority of waters impounded in our reservoirs contain no nitrates, nitrites or phosphates (which are considered by Dr. Mortimer and his colleagues at the Freshwater Biological Association at Wray Castle, to be of paramount importance in algal productivity). Still algal troubles constitute a

serious menace to filtration and chlorination processes in our province. Salem and Adoni have experienced very severe troubles from algae for several years, resulting in inefficient filtration and chlorination, and in pronounced taste and odour troubles. Chidambaram and Cocanada have been recently having such troubles.

The organic impurities added to the water by the natural death and decay of algae often impart a pronounced disagreeable taste and odour to the water. Filtration and chlorination become expensive and difficult. So, these have to be got rid of by suitable algicidal methods. A considerable amount of research work has been and is being done at the King Institute during the past two years, on the use and selective action of different algicides, such as copper sulphate, chlorine, ammonia, both alone and in combinations. When present in excess, algae are liable to cause discomfort in susceptible and delicate stomachs, as I have already mentioned.

Not so with the inorganic constituents present in water. Since the consumption of water involves every human being, the majority of whom have had no scientific training, we find that public opinions relating to the physiological effects of the mineral salts present in natural waters have been moulded without any consideration of the logic of the conclusions. Many results which have been accepted as truth are found, on closer examination, to have come from uncontrolled experiments which cannot, by any stretch of the imagination, be classified as scientific research.

When Louis the XIV of France became ill with typhoid fever and when his fate was uncertain for some weeks, his physicians administered a dose of antimony as a desperate measure. Soon he improved and then rapidly recovered and his recovery was attributed to the effects of the antimony on the basis of Plutarch's arguments. They little realized that the king recovered in spite of the antimony and not because of it. The same type of logic exists even today. We often hear it said that the tank water at Tirukkalukundram, or a well water near far-off Virudhunagar has miraculous healing powers, and that the maladies of thousands of people vanished with the drinking of this or that water. It is agreed by health authorities that human beings, in general, do not normally drink enough water. Now, in this case of the wonderful cures, what really happens is, the people who resort to these 'spas' alter their entire mode of living, and during the treatment play, rest and drink far more than normal quantities of water, and live in entirely different environments. We are well aware that many maladies rapidly respond to rest, recreation, change of air, and that waste materials are flushed from the system by an increased consumption of water. Regardless of these facts, the mineral content of the water is often unjustly and incorrectly boosted up.

Again, we often hear of waters being condemned as unsuitable, unpalatable, disease-producing, and so on, owing to the concentration of one or more inorganic mineral salts. Only a very few inorganic substances, I may say, have been really proved by scientific data to affect the public health in the concentrations in which they are found in natural water supplies. Some may affect the odour, colour, taste and turbidity. But, nearly all of these are practically innocuous physiologically, even in concentrations sufficient to produce intense colour, turbidity, odour or taste. No doubt, odour and taste may affect some persons psychologically to the extent that they may develop and exhibit physiological reactions. There is obviously much difference between a pure water and a physiologically safe water. I have always felt that it would be easier to define safe water than pure water. I do not know if any one of you here can give me a correct definition of pure water. It certainly is not H_2O in the liquid phase.

For æsthetic reasons, a drinking water must be as free of taste, colour, smell, and turbidity as possible, even though the substances causing them are harmless, *per se*, and even though the æsthetic quality of a water may change considerably without much significant chemical change. In other words, a water chemist must necessarily be a good psychologist as well as a water-purification expert. Thus, for instance, keeping water purification plants and laboratories spotlessly clean and as free of odour as possible, providing the water works with beautiful parks and footpaths, insisting on cleanliness and smart appearance of the staff, encouraging visits from the consuming public, all these may not affect in the slightest degree the purity of the finished water as issued to the public, but will certainly go a very long way in creating good will, confidence, and a feeling of security in the public towards their water supply.

I have already mentioned the physiological effects of bacteria in water on health. The data on physiological tolerance to inorganic impurities in potable water, are very conflicting and would, therefore, to my mind, bear cataloguing, if only with a view to provoking thought among the scientific workers I have the privilege of addressing to-day. The problem is, no doubt, very difficult to investigate and reliable information, based on accurate laboratory experimental data, is woefully lacking in many cases. Much that is known concerning physiological effects of mineral salts has been based on the experiences of consumers actually using the waters, rather than by exact laboratory studies. Only very approximate and necessarily imperfect data can be so obtained since human beings are not physiologically identical and a plethora of individual idiosyncrasies always comes into the picture. Again, susceptibility varies with age, sex, climate, occupation, and so forth. Finally, the effects of small traces of many substances

on the body's chemistry are still puzzling, even to the specialists. Not a year passes, but one of the ninety-two elements is added to the list of those having an important physiological bearing on health, zinc and fluorine being the most recent. Further, the physiological effect of simple metallic ions would probably be different from that of complex ions containing the same element.

Hard waters have been blamed for various disorders such as urinary concretions, arteriosclerosis, dyspepsia, constipation, goitre, diarrhoea, rheumatism and what not? There are critics who are never tired of saying that, due to the excess of calcium and magnesium contents in drinking water, our alimentary canals are getting coated with scales, as if they were boiler tubes. Hard waters have, however, been exonerated by several investigators both by mortality statistics and by experimental research. Some European authorities have recorded that, in communities where hard water is used for drinking, better teeth, body-weight and nerves are produced. Where lime is added to water as a corrective, I think the civic authority is doing the public a favour, since the one element most lacking in our diets is calcium. The human body requires approximately 0.7 to 1.0 gramme of calcium per day. Calcium taken with water would supplement that consumed with food. Large amounts of calcium salts would certainly affect the palatability of water but that is again a matter of individual taste. As a general rule, except for very few of the metallic ions, the taste factor will prevent consumers and even animals from injuring themselves physiologically by drinking such waters.

Textbooks lay down that drinking water should contain no caustic alkalinity. There, however, would appear to have been no facts or scientific data which would substantiate possible deleterious effects resulting from the use of waters containing small amounts of caustic alkalinity. It has been found that as much as ten parts per hundred thousand of calcium hydroxide alkalinity would be required to produce a distinct alkaline effect and that the dividing line lay between five and ten parts per hundred thousand. Like the calcium ions, magnesium in public water supplies is really of no public health significance. It affects the taste more than calcium, and, if you find a water is palatable, you may be certain that you are ingesting too much of magnesium. It is now known that the human body requires about one-third gramme per day of magnesium for normal functioning.

Salts such as sodium chloride and sodium nitrate pass through the intestinal walls, are absorbed by the kidneys and eliminated in the urine. This produces thirst, and by quenching the thirst we flush the salts from the system. Potassium nitrate seems to be more effective in this respect and the necessary dosage is small enough to include some natural waters. Any

form of nitrogen in water indicates organic pollution, but, where nitrates alone are found, we say that the organic matter has been oxidised to the fullest extent and rendered harmless from the sanitary standpoint.

All metals dissolve in water. Copper has, within the past ten years, assumed a very important rôle as a necessary supplement to iron for haemoglobin regeneration. It is an essential constituent of tissue cells. Prolonged heavy exposure to copper ions would, no doubt, damage the body. The traces left in potable water, as for instance after an algicidal treatment of the raw water in a lake, can certainly be in no way harmful to health. The body requires at least two milligrammes of copper a day and so 0.2 parts per million, which has been laid down as a permissible limit in water, is almost certainly therefore helpful, and not harmful. Chloramines in water supplies have not been proved to be physiologically objectionable. The suggestion made by the late Major Harold, Director of the Metropolitan Water Board of London in 1936, as to the continuous use of chlorine and ammonia along with copper in order to keep copper from precipitating out as copper carbonate and to secure a more sustained and prolonged algicidal action, has not met with disapproval, and does not therefore increase the copper hazard, so far as is known. The so-called cupri-chloramine treatment would mean, perhaps, very slightly more copper as distributed copper ions and copper bound in complex ions may have altogether different physiological effects.

Practically, everything in this world is poisonous and yet nothing is poisonous, if used correctly and in moderation. This applies to copper ions. I do hope that the time will come and soon come when public-health authorities would consider it to be advantageous biochemically to have traces of added copper in public water supplies. An American patent granted in September 1937 permits the incorporation of iron in milk. A number of biochemists and physiologists actually claim that the old-time method of cooking in copper and iron vessels was definitely of physiological importance as being beneficial to health. The use of copper vessels in Hindu households—now unfortunately going out of vogue in obedience to the dictates of fashion—had obviously, therefore, a hygienic and scientific basis. The lowest concentration of copper at which it can normally be tasted is reckoned at 1.5 milligrammes per litre.

Aluminium : The aluminium which gets into a purified water supply using alum for pre-treatment was believed, at one time, to be deleterious to health. It is no longer so; it has also now been definitely proved that food cooked in aluminium vessels is quite safe and fit for use. Arsenic is very seldom met with in water supplies. The amount getting into a supply from galvanized iron pipes is negligible. Lead

ions have had a bad reputation though some of it is not deserved. If the very small amount of lead which we ingest through water and food were as harmful as some people believe them to be, there will be many more cases of lead poisoning than are known to occur. No doubt, cases of plumbism have been reported in England, Germany, and France, traced directly to public soft water supplies. There is a widespread, but to my mind an erroneous, belief that lead accumulates steadily and is, therefore, a cumulative poison. This would mean that none of it is excreted. Some able chemists have published articles formulating conclusions on plumbism, supported by slender or no physiological evidence. Based largely upon these facts, 0.1 part per million of lead has been laid down as the permissible upper limit in water. Recent researches have, however, shown that the ingestion of lead ions in normal amounts does not result in a steady accumulation of lead in the body and that, apparently, an equilibrium is reached after a time, so that a substantially constant concentration of lead remains in the tissues, the daily lead output being equivalent to the daily lead intake.

Iron salts, both ferric and ferrous, are physiologically harmless to the system. The limit of 0.3 parts per million that has been prescribed in textbooks is based more on taste and colour considerations than for physiological reasons. Man requires 5 to 6 milligrammes of iron per day, and inorganic iron, as found in drinking water, can still be absorbed and utilized. The reason for keeping the iron content of potable waters low is an industrial, but certainly not a physiological, one.

A limit of 5 parts per million has been laid down for *zinc*. When the source of zinc contaminating the water, as commonly happens, is the galvanized iron pipe, the zinc compounds usually found in the water will be a mixture of oxide, hydroxide and carbonate, the last one perhaps predominating. Zinc carbonate, when present to the extent of 30 parts per million, would cause a noticeable milkiness in the water and would also give it an astringent taste. While there is no reason to consider this harmful, *per se*, you will realize that nobody will look at it, as a thirst-quencher. Foods and beverages, with the exception of simple or chlorinated drinking water, should not, however, be stored in zinc-lined or galvanized containers. And waters with a relatively high zinc ion content should not be used in making acid drinks, such as lemonade, as the resultant zinc citrate is a very poisonous substance.

Selenium, Boron, Manganese, Radium, Silver and Barium : These have all come in for comment and criticism in connection with drinking water supplies. Forage from seleniferous soils and drainage water from an irrigation ditch in Colorado, with a high selenium content, have

been stated to produce death among cattle. No authentic and scientific data have, however, yet been adduced, which would go to prove conclusively that selenium was the primary agent in the causation of these deaths. Boron ions are of great importance to plant life and even when present in concentrations high enough to affect plant growth, they are not likely to have any adverse physiological effect. This would appear also to be the considered opinion of the U. S. Department of Agriculture. Manganese, like iron, is usually removed from water for reasons which are not physiological. This element has, during recent years, come to be considered essential to normal bodily function. I have not come across any report in published literature of poisoning by radium from drinking waters. Silver, as most of you probably know, has been used in water sterilization during the past fifteen years and a process under the name of *Katadyn* has been patented by Krause of Germany. A consideration of the physiological effects of silver ions has consequently appeared on the canvas. I have often wondered, during the last ten or twelve years, ever since I had occasion to carry out some detailed research on the *Katadyn* sterilization process, if there was not a distinct possibility of the silver ions introduced into the water removing available iodine ions from water supplies, by precipitating the latter as the insoluble silver iodide. This would apply, *pari passu*, to barium, which occurs in appreciable amounts in the drinking waters of Switzerland. This might have some relation to the prevalence of endemic goitre in severe form in that country. A recent report in the *Journal of Endocrinology*, however, denies the existence of any relationship between the incidence of goitre and the silver and barium content of waters.

All the elements I have mentioned may, however, come into the picture in the future as fluorine has done, during the last few years in America and during the past three years in Madras.

Toxic qualities of fluoride in water used for drinking and cooking during the period of teeth calcification cause what is commonly known as mottled enamel, or specifically known as chronic dental fluorosis. This condition has been observed in approximately three hundred states of the United States of America. Sixteen of these states are west of the Mississippi river. Through investigations and research beginning in 1926, it is now established that the element fluorine combined as a fluoride, when present in a water supply in excess of about 1.0 part per million, affects the teeth of growing children, and thus a new problem in the water supply field has arisen. Ordinarily, fluoride in toxic concentrations is generally found only in underground water supplies and the problem is, therefore, in the main, confined to the smaller communities, although in certain areas relatively larger populous centres also are affected.

To most, if not to all, of you, the work that has been and is being done at the King Institute, during the last three years, on chronic endemic fluorosis must be familiar. The discovery in 1937, of a restricted area in north Nellore, where not only mottling of the enamel of the teeth in children, but also serious and disabling bone involvements in adults, were found to occur as a result of intoxication from fluoride present in drinking water, led to an intensive and extensive study of the various factors concerned in the production of such intoxication in that area. At the same time, a vigorous search was made for the presence of this element in samples of water received from all over the province, which resulted in the discovery of many more places scattered over the whole province, where the ground water supplies showed the presence of fluorides in sub-toxic and toxic amounts. The finding of fluorides in waters in our province has, indeed, been a disconcerting feature but has to be faced squarely. The removal of fluorides from water, when present in toxic amounts, has been engaging the attention of the King Institute and of several other agencies in other parts of the world. No satisfactory method of removal which would be at once economical and efficient has yet been evolved. To digress for a moment, some of you may probably know that wholesale iodisation of water supplies with sodium iodide was tried in a few cities of the United States in 1923 as a prophylactic measure against goitre, but it was soon abandoned in favour of direct treatment for those who suffered from iodine deficiency. The treatment of water supplies by the addition of moderate amounts of fluorides has similarly been suggested, during the past few months in America, as offering the most practical means for the prevention of dental caries in children. This is based on the results of certain observations made by some scientists who found that, in areas where mottled enamel was widely prevalent, the incidence of dental caries was very low.

Except for the protection of the teeth from dental caries, no other need for fluorine has ever been shown. Studies on fluorine have practically all been confined to fluorosis; the consequences of afluorosis, if any, are yet unknown. Sharpless and McCollum, the great nutrition experts, in the only published study of afluorosis, found no apparent injury to rats raised on low fluorine diets. Between mottled enamel and bone troubles from too much fluorine and dental caries from too little lies a field for much study by dieticians, physiologists, biochemists and doctors, so as to discover just how the diet and drink intakes of the individual contribute to the making and maintenance of good tooth structure.

I have so far attempted to show that very few inorganic substances, in the concentrations found in public water supplies, have been found, by scientific evidence, to affect the public health. I will now pass on to a consideration of what

may be called the pharmacology of water, that is, the positive and beneficial results to be expected from the use of water. This would mean that I consider water as a medicinal agent. Yes, I do and for valid reasons. The human body contains nearly 80 per cent of its weight of water in one combination or another. Water is a remarkable solvent of gases and salts and a palatable drinking water always contains these substances. People from one locality rarely like the water in another. The salts present in water, though very small in amount, impart a distinguishable taste to which we get accustomed.

Water is most essential to health. It aids digestion, elimination and the automatic regulation of body temperature. It is remarkable how quickly a glass of cold, or even more rapidly a glass of warm water reaches the skin and by evaporation cools the body, by dilution of the blood aids circulation, by dilution of the food aids digestion, and by the dilution of the waste products aids its excretion and elimination. The dilution of the food does not, as formerly supposed, dilute the acid and pepsin in the stomach. It increases their secretion and doubly aids digestion. Large quantities of water may be taken with meals with no harmful effects, as the benefits resulting therefrom include the flow of digestive fluids, the hastening and increasing absorption of food, leaving less in the intestines for bacterial decomposition. Drinking water allays also the pain due to hunger contractions. Thirst for water is, indeed, a response to the concentration of salts in the tissues, a lessened flow of saliva and the drying up of the mucous membrane. The elimination by the kidneys and the skin must, therefore, be promptly restored.

Digestive enzymes are known to act only in a fluid medium and it is only the dissolved or suspended material that is readily absorbed. As you know, it is only the moist air that is passed through the lung tissue. Hydrolysis and the reverse are constant processes in metabolism by which the protein molecules are converted into simple assimilable amino-acids. Even such a simple substance as sugar requires the addition of a molecule of water to transform the disaccharide molecule into two monosaccharide molecules which are readily absorbed and utilized by the body. Few chemical or biological reactions can occur without water. Perfectly dry formaldehyde gas or sulphur dioxide would have no effect on dry bacteria, and absolute alcohol has been shown to be equally ineffective as a rapid bactericide. But, with moisture, each of them becomes a potent and quickly-acting germicide.

Waters containing gases, carbon dioxide or hydrogen sulphide in solution are often used for their medicinal effects. Carbonated water, natural or artificial, stimulates the stomach into increased activity by a mild irritation, thereby

increasing absorption and necessarily, therefore, elimination. It aids in expelling flatulence from the stomach and intestines. It is more palatable and sharper to the taste than ordinary water, and is therefore often used in fevers or where extra elimination is required.

I believe I made a passing reference to reputed cures from the use of certain tank and well waters. The real thermal springs contain a small proportion of H_2S and alkaline sulphides, and are consequently recommended for respiratory and skin diseases, syphilis, gout, rheumatism, and even metallic poisoning. It is, indeed, more than probable that all the benefits derived from such waters are due to the heat of the water and to the prolonged and frequent baths ordered by a physician, rather than to any specific effect of the sulphur. The gaseous content, which, when it emanates from a sewer, is considered obnoxious, is here indirectly a benefit, as it aids the mind to respond to the action of the water containing it.

If we pause to consider the minute amounts of the substances contained in water and attempt to assess the effects on the system of ingesting them, only a fertile and vivid imagination or a supreme faith in the principles of homeopathy, as exemplified by its fractional dosages, will recognize any value in those substances.

To all intents and purposes a good and safe water for drinking requires only bacteriological purification except in cases where some absorbable poison is present. Most forms of purification, therefore, aim at a reduction, if not elimination, of the bacterial content. As regards very hard waters, however, they are considered objectionable as cleansing agents, on account of their being wasteful of soap. The soap destroyed by hard water is nearly ten times the weight of the constituents responsible for the destruction

Palatability and cooking properties would be very good guides in the choice of a good drinking water supply for any community. People would automatically reject as unfit, a water which has a very high solid content, which is brackish or unduly alkaline, which does not boil dal or which produces a discolouration of rice cooked in it. If, however, there is no other and better water available in any locality, they will take their choice with Hobson. Human instinct is seldom found to have failed in the assay of potability of water from the chemical point of view.

I may conclude, therefore, that any adventitious circumstance, under which water is used, or any peculiar property, real or imaginary, which will encourage a more liberal use of water, either internally or externally, is not to be underrated in its bearing on health. The presence of pathogenic organisms responsible for water-borne epidemics would constitute almost the only important factor to reckon with in the use of God's greatest gift to man, namely water.

LECTURE ON CO-ORDINATED EFFORT IN HYGIENE*

By W. H. CRICHTON, M.B., CH.B., D.P.H.

LIEUTENANT-COLONEL, I.M.S.

Chief Health Officer, Delhi Province, New Delhi

THE health of a nation depends on the health of the individuals composing that nation. The object of hygiene or preventive medicine is to build up the health of the nation by the care of the health of the individual. The working capital of the individual is his capacity to pull his weight in the ship of state. Once that capacity has been impaired, instead of being an asset to the state he rapidly becomes a liability. Anything therefore which tends to render the individual fitter for the function he serves in life, or, on the other hand, anything which may impair that function, is of vital interest to the student of hygiene.

It is manifestly absurd therefore to suppose that hygiene is a subject restricted to the collection of vital statistics, to sanitation and conservancy, and to the control of infectious diseases, because hygiene must necessarily be concerned with every circumstance affecting the individual. Indeed hygiene aims at the protection of the individual from *all* disease, not only by attention to his environmental and personal hygiene, but also by raising his powers of resistance to disease.

Sir George Newman has said '... we have come to realize that our first line of resistance to disease is the health of the individual. Thus, although environment, infection and the accidents of life and disease undoubtedly exercise their influence upon him, directly or indirectly, it is the care of his own body, with its growth and development, its resistant soil and its natural powers of defence against disease which form the basis of good health and of scientific prevention'.

In the practical application of these principles, mere perfection in the environmental sphere would result in little advantage if the circumstances attending the birth, the home, the personal habits, the occupation, recreation and happiness of the individual were to be ignored. Provision must therefore be made for his care to be undertaken at the earliest moment in his existence; in other words, through care of the expectant mother. His birth must be conducted under the most favourable conditions possible; his after-care and that of his mother must be supervised by skilled workers, and, later on, arrangements have to be made for his care before his going to school, during school life and, later on still, when he is at work.

The successful fulfilment of this policy demands the closest co-operation, not only between preventive and curative medicine but

also with the authorities concerned with education, with agriculture, with the care of cattle, and with the means devised for the amelioration of the economic status of the people. These beneficent services must work as a team towards what must be their common ideal, namely, the betterment of the people. It is no good, for instance, for the Agricultural Department to recommend a method of manure conservation or storage if this happens to encourage the breeding of flies. The boon of an enriched soil and the prospect of better harvests would be nullified by the certainty of an increase in the diseases which are spread by flies. Similarly, as has often happened in the past, the benefits conferred on a people by the construction of new roads have been destroyed by the creation of many large breeding places for mosquitoes in the excavations made for the building of the road. Effective co-operation between the health and engineering services would prevent such a calamity.

This consciousness of the existence of other beneficent services and knowledge of the manner in which they can assist in the common cause is an essential requirement in any health or other social worker. Without it, no one can ever expect to see the fruits of his or her labours. Thus, for instance, it often happens that even within one department, a worker limits his sphere of activities so strictly to his own speciality that he literally ignores factors which his training teaches him to recognize as injurious. A lady health visitor, for example, who enters a house on her home visits tends the mother and the child, and then walks out having completely ignored clouds of flies, or myriads of mosquitoes or badly ventilated rooms, or bad drainage is really guilty of gross dereliction of duty. It does not matter whether she herself is capable of applying the remedy, or whether it be a matter which should be referred to another authority, she is still responsible for taking appropriate action to remove an influence which is detrimental to the health of the individual. Indeed the interest of the health visitor should go far beyond the immediate confines of health matters. She should take an intelligent interest in the economic condition of the family she is looking after, and she should be in a position to advise the housekeeper on village or other industries by which the family income could be augmented, so as to make it possible for a shortage in essential foodstuffs or adequate clothing to be remedied. She should be aware of such serious calamities as bad or poor harvests, or of ailments among the cattle, and she should not only suit her advice to the capabilities of the people, but should also see that appropriate help is forthcoming, if necessary, from the department concerned; either in the form of *taccavi* or loans from Government, or in the form of fodder, or whatever measures of relief Government provides. It is these opportunities of intimate contact with the family in

*A lecture delivered at the Lady Irwin College, New Delhi.

the home that gives the trained lady health visitor the proud and important place she occupies in the practical betterment and education of the people.

Among the many pitfalls which beset the path of the social worker intent on the amelioration of the people, nothing is more certain to lead to failure than the giving of advice which cannot be acted upon. For instance, it is common knowledge that one of the most serious deficiencies in the average Indian dietary is vitamin A. Now the most effective remedy for this shortage is the encouragement of vegetable cultivation. Green leafy vegetables as you all know contain a very good proportion of this essential commodity and therefore all that is necessary, one would think, is to advise intense vegetable cultivation. But it is useless to do this if the people concerned are ignorant of the manner in which vegetables should be grown. In this case reference to the agricultural authority will enlist the assistance of that department in providing information and instruction in the subject.

The inculcation of sound practical hygienic principles and the correction of bad habits at a tender, and therefore more receptive, age involves the assistance and co-operation of the educational authorities; the improvement of communications so as to enable health workers to get to the people they are looking after, or to allow villagers access to welfare centres or hospitals, demands the help of the engineering services; improvement in the output of milk, both for nutritional as well as for economical reasons, necessitates the active help of the veterinary department; the dissemination of knowledge on all matters affecting the welfare of the people demands the assistance of the press and the radio; the correction of wasteful customs and the encouragement of thrift calls for the aim of the co-operative services with their banks and their thrift societies; the uneconomical division of landed property demands expert treatment by the consolidation authorities; while early notification of the outbreak of infectious disease demands the co-ordinated effort of the public, the medical practitioners and the police authorities. What therefore is wanted is a standing committee or board of all heads of departments which is known as the Central Officers' Board whose function it is to co-ordinate the efforts of each department.

No health worker can afford to do without the assistance of the revenue department which has so much influence in the *dehat*. I am not suggesting that compulsion should be brought to bear. Pressure, let alone compulsion, is foreign to Government policy and the success of welfare plans depends entirely on the willing co-operation of the people. Ultimately that can only be achieved by the spread of education, but in the meantime the active interest of the revenue officials in the schemes put forward will do much

to encourage the villagers to take them up. Another way in which the department can help is by prevailing on *lambardars* and other village notabilities to set a good example by adopting the recommendations made by the health or other authority for the improvement of the welfare of the villagers. It is no good inducing the *chamars* and *bangis* to take up house improvements, while the homes of the *jats* are left in their original state of filth and insanitation. Not only do their houses and their habits generally need improving just as much as those of the lower classes, but the fact of their taking them up naturally encourages the rest of the village to do so. *Lambardars*, *jagirdars*, *sufed-poshes*, and retired government and army officials living in comfort and ease on their pensions owe at least this much to the state that they should give a lead to the villagers in adopting the measures directed to their improvement.

Of all the arguments which may be used in the persuasion of the people, none is more convincing than the force of example. There is therefore nothing more discouraging than to see a health worker who is slovenly or even grubbily dressed, or one whose house is ill-kept, ill-ventilated or full of flies and smoke, or whose children are smothered in dirt or have streaming eyes or noses. Similarly no school teacher can hope to carry any conviction in teaching personal hygiene if his or her own appearance leaves much to be desired. It should be axiomatic that every social worker should practice what he preaches and take a personal pride in the principles he practises. This carries conviction, breeds respect and raises the dignity—the *izzat*—of those who follow these practices. If more persuasion were needed, this is provided by the health and sturdiness of the children of those who take the trouble to learn, and by the comparative freedom of the family from the ailments which assail the average villager's family. Once the desire is created in the individual to live in a manner calculated to promote good health the battle is won. Social workers, and particularly public health workers, must remember that they are the instruments through whom this much needed education can be spread in the present circumstances, and that however difficult or humble their task, they are playing an important part in building up the nation's health, and with it, its self-respect.

There is much that needs to be done in India but the magnitude of the task should not deter any sincere worker. No estimate has ever been made of the financial loss debitible to ill-health in India, but when it is realized that in Britain the total economic burden of ill-health due to loss of work is estimated at something of the order of £300,000,000 a year some idea may be gained from this of the astronomical figure which must apply to India. Nevertheless, of the complex array of health services which have been built up in Britain, and which now cost

the nation some £113,000,000 per annum, none had more than a vestigial existence 70 years ago. With education, good-will and team work, there is no reason why the same measure of success should not be attained in India as has been achieved in Great Britain during the last generation which has changed a 41 per cent

C 3 nation into one which is over 80 per cent A 1.

The country must learn to pay more for the privilege of good health. In Britain the health services provided cost some £2-10-0 per head, or Rs. 33. In Delhi Province we only spend Rs. 3-8-0 per head.

A. R. P. WORK IN INDIA

HANDBOOK ISSUED BY GOVERNMENT

THE Home Department of the Government of India have issued a handbook, the first of a series on A. R. P. in India, giving a broad outline of the principles which may be followed in regard to A. R. P. throughout India.

The object of air attack is to dislocate the war effort of a nation. To attain this, an enemy will deliberately attack targets of military importance and may also indulge in indiscriminate bombing of the civil population. The primary responsibility for active defence to resist an enemy lies with the defence services, but it is essential to have available a nationwide organization to minimize the effects of air raids which may penetrate the active defences. Hence the necessity for air raid precautions.

The most effective weapon used by modern air forces is the high explosive bomb which may weigh from 25 to 3,000 lb. Damage is mainly caused by the blast of the explosion and by the fragmentation of the shell of the bomb.

The small incendiary bomb will normally pierce the ordinary type of roof and ignite the top storey. It is therefore essential to clear all upper floors of inflammable material. But reinforced concrete six inches thick will resist incendiary bombs of 2 lb. weight.

The control centre is the nerve centre of the local A. R. P. organization. It will receive reports of air damage from wardens and police and will issue the necessary directions to the various services, so that they can be despatched to the scene of the occurrence. All messages that come in either by hand or telephone will be recorded and the position of all air raid damage shown on a large area map by the insertion of differently coloured flags.

The primary responsibility for resisting the enemy's efforts lies with the active defence services. In order to ensure close co-operation between those services and the A. R. P. organization, it is imperative that where cities and cantonments are adjacent to each other, the service passive air defence and civil air raid precautions schemes should be co-ordinated with particular reference to the warning system and lighting restrictions. Local military and naval authorities will be glad to render assistance in the carrying out of practices and observations of their effectiveness.

Drastic lighting restrictions are an important feature of the precautionary measures to be taken as a form of security against air attack. The aim is to secure that, as far as practicable, hostile aircraft passing over the country at night would see no lights which might serve to guide them to a particular objective or assist them to determine their position. The restrictions therefore impose as a permanent condition general darkening in the cities classed as vulnerable and there is an obligation on those controlling lights, i.e., the police and air raid wardens, to observe and enforce the restrictions.

From the outbreak of the war all illuminated advertisements will be prohibited in vulnerable areas and all external lights will have to be shaded or extinguished according to local rules. In the case of internal lights complete invisibility from outside can be secured by the darkening of windows, skylights or

glazed doors. This can be done by fitting of blinds, covering the whole window with opaque paint, loosely fitted shutters of plywood in windows and automatic steel shuttering. In factories, it may be practicable to carry on work with lamps of lower power or so shaded as to throw light on the machine or bench.

The handbook also deals with air raid wardens, fire fighting and medical arrangements, rescue parties, maintenance of vital services, anti-gas protection and decontamination and training of A. R. P. personnel.

ALL-INDIA OPHTHALMOLOGICAL SOCIETY*

SEVENTH CONFERENCE AT BANGALORE

THE Seventh Conference of the All-India Ophthalmological Society was held at the Mysore Medical Association Hall, Bangalore, on Friday, Saturday and Sunday, 20th, 21st and 22nd December, 1940.

The conference was formally opened in the town hall by Sir Mirza Ismail, K.C.I.E., Dewan of Mysore, who conveyed a message of cordial welcome from His Highness the Maharajah of Mysore to the delegates to the conference.

The chairman of the reception committee, Dr. B. K. Narayana Rao, in welcoming the delegates once again to Bangalore referred to the anomalous position of the standards of vision in public services in the different provinces of India and drew attention to the problems of eye diseases due to nutritional defects and to injuries due to the rapid industrialization of the country.

In his address, the President, Dr. R. P. Ratnakar of Bombay, dealt with some of the ophthalmic problems engaging the attention of the profession and offered some suggestions to meet the difficulties.

The scientific session commenced with a collection of papers on trachoma in which the treatment of the disease received the greatest attention, the consensus of opinion favouring the use of sulphanilamide orally, silver salts locally and tarsectomy in advanced stages of the disease.

Dr. Bhaduri (Calcutta), who opened the discussion with a paper on trachoma in Bengal, referred to the low incidence of trachoma in Bengal, especially amongst the indigenous population, and described a few cases of acute onset with bacteriologically negative conjunctiva. He further drew attention to the persistence of active pannus or its recurrence in some cases with complete fibrosis of the conjunctiva.

Dr. Sathaye (Poona) referred to his experience of the disease in the Bombay Presidency and mainly dealt with the treatment of the disease. He also read a paper on surgical treatment of the disease by Capt. Gokhale (Poona), in which the author strongly advocated tarsectomy in advanced cases.

Dr. Shroff (Bombay) found silver iodide very efficient in curing trachoma in the first two stages and advocated tarsectomy for advanced cases.

A paper by Dr. Mitton (Delhi) on the administration of sulphanilamide in trachoma referred to her experience in a large number of cases with encouraging results. She had followed the dosage and period of treatment adopted by Dr. H. Gradle of Chicago.

* Received for publication on 17th February.

APRIL, 1941]

Dr. Krishna Rao (Bangalore) spoke about the sulphanilamide treatment of trachoma as followed in the Minto Ophthalmic Hospital, Bangalore. He concluded that the results so far found were favourable.

Several members took part in the discussion on these papers.

On the 21st, after an interesting series of visits to various factories in Bangalore in the morning, a crowded programme of papers was got through in the afternoon. For want of time, some papers of members who were not present were taken as read. Two of these papers referred to two interesting cases of Boeck's sarcoidosis. As no materials were available in these cases for confirmatory evidence on histological grounds, the diagnosis rested mainly on clinical examination.

The papers read at this session included the following:—

1. Epithelial plaques of the conjunctiva by Dr. M. Ponnambalam and Dr. K. S. George.
2. Bloody tears—case report by Dr. M. Ponnambalam and Dr. K. S. George.
3. Membranous conjunctivitis in vaccinia—case report by Dr. B. N. Bhaduri.
4. Dyscoria—case report by Dr. M. Ponnambalam and Dr. M. B. Sundar Rao.
5. Relative and Arneth-Bonsdorff counts in hypopyon ulcers by Dr. K. Sundaresan.
6. Boeck's sarcoidosis by Dr. E. V. Srinivasan.
7. Surgical diathermy for the relief of increased tension in blind glaucomatous eyes by Dr. B. P. Nanavati.
8. What looks like a case of Boeck's iritis by Dr. K. Sundaresan.
9. A case of organized haemorrhage of the Cloquet's canal in one eye with remains of persistent hyaloid artery in the other by Dr. M. S. Mehkri.
10. A case of dermoid cyst in the inferior medial angle of the orbit by Dr. M. S. Mehkri.
11. Case report of exudative retinitis with detachment of the retina by Dr. M. P. Krishna Rao.
12. A case of papilledema by Dr. M. P. Krishna Rao.
13. Dermoid of the cornea—case report by Dr. B. N. Bhaduri.

On the last day of the conference an all day outing was arranged to the Bangalore waterworks at Thippa Gundana Halli, about 20 miles outside Bangalore.

The general meeting of the society was held at this place during the lunch hour. Three papers were also read during this time. These were a paper on 'Blindness in India' by Lieut.-Colonel E. O'G. Kirwan, I.M.S., which was read by Dr. Bhaduri, one on 'Factors that disturb the natural immunity and eye diseases' by Dr. C. N. Shroff, and one on 'An easy method of dealing with secondary glaucoma due to morgagnian cataract' by Dr. E. V. Srinivasan.

Dr. G. Zachariah mentioned the necessity for a uniformity in standards of vision for the various services throughout India and suggested the appointment of a committee to go into the question. A sub-committee was accordingly appointed.

At the general meeting, new office-bearers were elected for the following year:—

President.	Dr. R. P. Ratnakar.
Vice-Presidents.	Lieut.-Colonel E. O'G. Kirwan, I.M.S. (President Elect).
	Dr. E. V. Srinivasan.
Secretaries.	Dr. G. Zachariah.
	Dr. B. N. Bhaduri.
Treasurers.	Dr. K. N. Karanji.
	Dr. C. N. Shroff.

It was decided that the Adenwalla medal will, in future, be awarded to the best essay written by any medical man in India on a subject to be notified hereafter by the committee.

It was also decided that a quarterly ophthalmic journal will be published by the society. Dr. B. P.

Nanavati and Dr. S. N. Cooper were selected to be the joint editors of the journal.

FIGHTING DISEASE ON THE FRONTIER

OVER 500,000 out-door patients were treated in civil hospitals on the North-West Frontier border in 1939-40, showing an increase of over 40,000 as compared with the previous year.

In the Khyber Agency the building of a new hospital at Landi Kotal has been sanctioned. Forty thousand out-patients and 200 in-patients were treated in the existing dispensary. At the Jamrud dispensary the figures were 25,000 and 200 respectively.

In the Kurram Agency there are hospitals at Parachinar, Alizai and Sadda. The latter attracts tribesmen from Tirah as well as inhabitants of the valley. These hospitals between them treated 140,000 out-door cases and 1,100 in-door.

In the Malakand Agency there is a hospital at Malakand, a Swat State Hospital at Saidu, and dispensaries at Chakdara, Thana, Dargai and Loe Agra. Three thousand male and 1,000 female in-patients, and 11,000 male and 5,000 female out-patients came for treatment. In the Chitral State there are Government hospitals at Chitral and Drosh. Eighteen thousand out-patients and 300 in-patients were treated. The reluctance of the Chitralis to face surgical treatment is being overcome by the patient efforts of the medical staff, whose extensive touring was much appreciated by the villagers. Goitre is widespread, and diseases due to a poor diet are common.

The small civil dispensary at Fort Lockhart in the Kohat district provides treatment for tribesmen from both sides of the Samana hills, and the hospital at Gurguri for Wazirs and Khattaks. Thal is the rendezvous of large numbers of people from the settled districts, the tribal areas, and Afghanistan, and the existing private dispensary, which receives a Government subsidy, is to be replaced by a public one.

In the Dera Ismail Khan tribal area, the hospital at Jandola attracts many Bhitanni and Mahsuds tribesmen, rather over 9,000 out-patients being treated there. A scheme to electrify the building is under consideration, and this year four small and badly ventilated rooms were converted into two large wards. Although there is no provision for the segregation of the sexes, the proportion of women to men treated was as much as one to three. The Frontier Constabulary hospital at Drazinda, which is placed at the disposal of the Sherani tribesmen, treated 30,000 cases.

WOMEN'S HOSPITAL

At Tank the women's hospital of the Church Missionary Society, managed by three European ladies, is visited by large numbers of Wazir and Mahsud women from Waziristan, as well as Bhitannis and other clans. This medical missionary work has aroused no protest from the Mohammedan tribesmen, indeed the respect which they all have for the devoted work being done was shown during the Shabi Khel Mahsuds' conflict with Government, when the chief leader of the opposition sent a message to the lady doctors saying that he had given strict orders to his followers that in no circumstances were they to be molested.

In the Hazara district the hospital at the constabulary fort of Oghi was patronized by tribesmen from the Black Mountain and the Indus Valley region, amongst them being 15 men who had received wounds in local warfare.

The Miranshah hospital in North Waziristan enjoys a high reputation among all tribes of the Agency particularly for the cure of gun-shot fractures, a common injury where most disputes are settled with firearms. The modern closed treatment of such wounds has achieved considerable success, the foul smell normally regarded as the drawback of this treatment being apparently less obnoxious to the tribal nose than one would expect. Successes have also been achieved in

the treatment of cataract and trachoma. Unsettled conditions have made it difficult for the medical officers to visit villagers; when they have done so the entire population has turned out for inspection. The Wazir, who believes that a handsome face attracts a fair lady, is beginning to realize the value of vaccination to prevent smallpox.

In South Waziristan there are hospitals at Razmak, Wana, Ladha, Sarwekai, Sararogha and Tiarza, and dispensaries at Kotkai, Chagmalai, Splitoi and Tanai. The tribesmen took full advantage of these facilities, but disturbed conditions prevented doctors visiting villages at a distance from the roads, though roadside clinics were carried on as far as possible.

INDIAN DRUGS FOR EXPORT

WAR STIMULUS TO INDUSTRY

THE following drugs are being produced in India in sufficient quantities for export, according to the Director-General, Indian Medical Service:

Alcohol, alum, belladonna, carbonei dioxidum, chirata, digitalis, ferri sulphas, gum indici, hyoscyamus, Jalapa, kaolinum, lobelia, nux vomica B.P., oil vegetable hardened, oleum arachis, oleum eucalypti, oleum hydnocarpi, oleum morrhuae (substitute from shark liver oil), oleum ricini, oleum terebinthinae, opium and crude morphine salts, podophyli resina, rheum (rhubarb), santoninum, scilla, sennæ folium, B.P., strychninca hydrochloridum.

Oral and Medical Treatment of Gonorrhœa in the Male

By P. S. PELOUZE, M.D.

(Abstracted from the *Journal of American Medical Association*, Vol. CXIV, 11th May, 1940, p. 1878)

FOLLOWING the introduction of sulphanilamide a number of other sulphonamide derivatives have been produced, some of which have shown as much curative value as has sulphanilamide itself. One, sulphapyridine, has been spoken of even more glowingly and there is accumulating evidence to suggest that it is somewhere between 25 and 50 per cent more efficient than sulphanilamide. Its cost, however, is such that it is far beyond the financial reach of dispensary patients. To date, only sulphanilamide and sulphapyridine are on the market. It is earnestly to be hoped that a way may be found to reduce the price so that both the poor and the near poor may share the benefits.

At least two of the other sulphonamides now being experimentally used for gonorrhœa have shown an unfortunate tendency to produce peripheral neuritis.

Because of the unfortunate limitations to the general use of sulphapyridine it might be just as well to consider sulphanilamide rather fully, realizing that what is true of it from the standpoint of toxicity and other features, aside from the obtainable percentage of cures, apply equally to the former drug in equal doses. It, however, should be stated that sulphapyridine rarely is given in larger doses than 4 gm. in the twenty-four hours. And no dissertation on any sulphonamide derivative used so far would be complete without the warning that these preparations bear toxic possibilities.

Beyond a doubt, much of the toxic picture could be obliterated if sulphanilamide medication was stopped just so soon as it obviously was failing to produce cure. Practically all the favourably influenced males are symptom free by the end of the fifth day. If such a change has not occurred in that length of time it is extremely rare for further administration to be of benefit. In other words, it is perfectly safe to consider the patient who is not almost entirely free from symptoms then as a sulphanilamide failure and stop the drug.

Later courses of sulphanilamide almost never have a controlling effect in the same case, but it has been shown that sulphapyridine used for those patients who have obtained no curative effect from sulphanilamide not uncommonly exercise a favourable response.

There are many schemes of dosage for sulphanilamide in this disease, most of which have been aimed at a prompt high concentration of blood which later can be maintained on a reduced dosage. That blood concentration is not the sole consideration is shown by the experiences of Van Slyke, Thayer and Mahoney, who numbered some of their successes among cases showing the lowest blood concentrations and some of their failures among those in which the concentration was enormous.

Perhaps the most common scheme of dosage in use in ambulant patients is 80 grains a day for two days, 60 grains a day for the next three days and a later continued daily dosage of 40 grains. Many clinicians consider this too high and use 60 grains a day for three or four days and a maintenance dose of 40 grains a day thereafter. Others claim successes in equal measure on 45 grains a day for eight days and a maintenance dose of 20 grains a day thereafter. In bed patients, on whom the most dependable figures have been obtained, the initial dose was 120 grains a day for several days and then a gradual reduction of the dosage. To such patients the drug has been given in doses so spaced as to prevent low blood concentration during the night. Some have given larger doses at bedtime to ambulant patients for the same purpose. Many administer sodium bicarbonate in half the quantity with each dose.

Sulphanilamide should be discontinued if it produces any marked symptoms of toxic action, and it never should be given to patients who cannot be seen by the physician at most every forty-eight hours. Because of its possible production of dizziness, it should be given with extreme caution or not at all to men in hazardous occupations.

From the foregoing it will be seen that much of the problem remains exactly as it was before the introduction of sulphanilamide. There is the same need for an understanding of the disease itself and those methods of treatment which have stood the test of time. By a sensible combination of the two one has no need for depression or the development of a defeatist attitude. In fact, the physician is standing on far better ground than he did a short time ago, for it has been shown beyond any doubt that, even in those cases in which sulphanilamide does not bring about cure, its use early in the disease almost invariably makes it a milder disease thereafter and enormously reduces the likelihood of serious complications.

There are a number of facts that one should have constantly in mind regarding gonorrhœa. These might be stated briefly as follows:

1. Gonorrhœa is a disease of tissue penetration by the gonococcus wherein the germs reach tissue depths far out of the bactericidal powers of the drugs applied locally.
2. Cure is brought about by the patient's own tissue processes.
3. These can be enhanced by the direct application of mild chemical solutions to the infected regions and the promotion of better drainage.
4. Certain factors greatly reduce or obliterate these tissue responses, namely the ingestion of alcoholic beverages, sexual excitement, prolonged physical exertion and the inhalation of the fumes of alcohol, ether and perhaps some other substances.
5. Thus the one 'priceless ingredient' of all curative effort is patient co-operation to the end that these circumstances do not occur.

6. The greater the patient co-operation and the gentler the treatment (within limits), the milder and shorter is the disease and the fewer are its complications.

7. Treatment of this disease is entirely empirical in that we have not the slightest knowledge of just how it accomplishes its purpose.

8. Traumatic methods have no place in treatment; they prolong disease and precipitate complications.

9. Aside from sulphanilamide and its companion drugs, oral medication has been signally lacking in curative influences.

10. Some drugs, notably oil of santal, at times reduce discharge and discomfort, though they exercise no definite curative effect.

Many drugs have been employed for the local treatment of gonorrhœa, but year after year these gradually have been reduced in number until to-day we find but a few that are in general use. Countless numbers of these have fallen into disuse because of the extravagant claims that their introducers made for them or the fact that many of them bore proprietary names and differed so little from pharmacopœial drugs that their higher cost was not merited. I need fear no successful contradiction if I make the statement that none of the proprietary preparations of silver are of more value in the local treatment of this disease than are those in the pharmacopœia. Of the drugs most commonly used for local treatment to the mucous membranes of the urinary tract, together with their most appropriate strengths, might be mentioned those in the accompanying table.

There are times when it is wise to use oral sedatives either for the prevention of penile erections or for the relief of pain and vesical discomfort. For the former, sodium bromide in doses of from 10 to 15 grains (0.6 to 1 gm.) at night is rather commonly used. For sensory disturbances some form of opium is to be preferred. Of these, camphorated tincture of opium in drachm (4 c.c.) doses or tincture of hyoscyamus in from 15 to 20 minim (1 to 1.3 c.c.) doses usually suffice for the milder symptoms. For the more severe, codeine in from one-fourth to one-half grain (0.016 to 0.032 gm.) doses, morphine in from one-eighth to one-fourth grain (0.008 to 0.016 gm.) doses or rectal suppositories containing one-fourth grain of belladonna and 1 grain (0.065 gm.) of powdered opium may be required. Some urge the value of mild alkalies and more generally use either potassium acetate or citrate in doses of from 10 to 20 grains (0.65 to 1.3 gm.).

Drugs most commonly used for local treatment of gonorrhœa

	Strengths	Best
Potassium perman-	1 : 10,000 to 1 : 3,000	1 : 8,000
ganate.		
Mild protein silver ..	3 to 10 per cent	5 per cent
Strong protein silver ..	0.25 to 1 per cent	0.5 per cent
Acriflavine ..	1 : 5,000 to 1 : 1,000	1 : 3,000
Silver nitrate ..	1 : 10,000 to 1 : 1,000	1 : 5,000

Regarding the use of chemicals to the urethra and bladder by means of injections or irrigations by hand, there are a number of facts that should be borne in mind, the most important of which are as follows:

1. One or two applications in twenty-four hours usually is of greater benefit than a larger number.

2. All applications cause a purulent response from the anterior urethra and if their response lasts more than an hour or two the chemical is too strong for the given urethra and its strength should be reduced.

3. All chemicals used over too long a period have a tendency to keep up the urethral discharge.

4. The appearance of many epithelial cells in the urethral discharge is positive evidence that the medication is too strong or has been used for too long a time.

5. Fluids should not be injected into the posterior urethra if only the anterior portion is infected.

6. If fluids are to be held in the anterior urethra without being forced into the posterior urethra, the quantity injected should not exceed 6 c.c.

7. If fluids are to be injected into the posterior urethra, it should be done either by low hydrostatic pressure or with the utmost gentleness by means of a bulb syringe with a blunt nozzle.

8. No instruments of any kind should be passed into the canal while the gonococcus is present.

9. Sudden marked changes for the worse in the patient's condition almost invariably denote poor co-operation.

10. The two glass test, properly interpreted, is the simplest way of following the course of the disease.

11. The amount of clouding of the voided urine is a safe index of the activity of the infection.

12. Even in the most favourable of the sulphonamide cases the urine becomes clear before the disease is cured. Hence a clear urine is by no means an evidence that the gonococcus has been eradicated.

As an appropriate scheme of treatment for this disease it is felt that a sulphonamide derivative in one of the suggested dosages might be given for the first five days. If at the end of this time the patient has no urethral discharge and has a clear urine, a maintenance dose of the drug should be continued for ten days longer, in the absence of toxic symptoms. If the local symptoms do not abate or if the drug must be stopped, the accompanying plan should be followed.

PLAN OF TREATMENT

Anterior urethritis.—1. After urination the anterior urethra is cleansed with 1 : 10,000 to 1 : 5,000 solution of potassium permanganate either by low pressure irrigations or by gentle hand injections by means of a syringe.

2. By means of a bulb syringe not more than 6 c.c. of a 5 to 10 per cent solution of mild protein silver (U. S. P.) or from 0.25 to 0.5 per cent strong protein silver (U. S. P.) is injected into the urethra and kept there for five minutes. (The weaker strengths are better.)

3. Such treatments are carried out daily until there is no urethral discharge and then every other day. If the latter interval proves too long, as evidenced by the recurrence of discharge, daily treatments should be resumed for a few days and the interval again increased. Later, when safe to do so, the interval is increased to every third day.

4. If the patient cannot visit the physician frequently enough for this regimen to be carried out, a one-eighth ounce glass syringe and 0.25 or 0.5 per cent solution of strong protein silver (U. S. P.) is ordered with instructions to use it twice a day.

5. It is safest not to try the ordinary tests of cure for patients under either of these two plans of treatment before the end of the fifth week in the most favourable of cases. (This does not apply to the real or seeming sulphonamide successes.)

6. Every effort should be made to obtain the patient's co-operation and no local treatment should be placed in his hands without the most explicit instructions as to their proper use.

7. Such patients should have described to them the symptoms of posterior urethral involvement and told to stop local treatment and present themselves at the physician's office if they occur.

Posterior urethral involvement.—1. Local urethral treatments should be stopped until the acute symptoms subside.

2. Acute symptoms can be controlled with sedatives and hot hip-baths.

3. After vesical comfort has been regained entirely, low pressure intravesical irrigations of potassium permanganate solution should be given at intervals of two or three days.

4. Prostatic or seminal vesicular manipulations should be avoided until the second glass of urine is clear and the first is almost clear.

5. One should start massage with the very gentlest prostatic strokings and, if it causes a return of urethral discharge, one should wait a week before trying again. If it causes no such recrudescences of symptoms it should be repeated at intervals of from three to four days, the pressure being gradually increased at subsequent visits but never reaching a point of roughness.

6. The massages should be continued at these intervals until the prostatic secretion is free of pus.

7. During the first month or six weeks of prostatic massage it is well to carry out a preliminary intravesical irrigation, some of the solution being left in the bladder to be voided after the massage. If after this time the irrigations are discontinued, there rarely will be any shreds in the urine when the patient is ready for dismissal.

TESTS OF CURE

The use of sulphanilamide in gonorrhoea has thrown a deep cloud of uncertainty over the older tests of cure. So true is this as to make it absolutely necessary to use methods that formerly were little needed in the male. Before this drug came into use one was almost 100 per cent safe in pronouncing a patient cured who had no urethral discharge and in whom a discharge could not be made to occur by the ingestion of alcohol, sexual excitement, the passage of a sound with massage of the urethra or whose discharge occasioned by a provocative injection of 1 per cent silver nitrate failed to show the gonococcus.

On those patients seemingly cured by sulphanilamide these simple procedures are sadly lacking in value, for such patients rarely experience a recrudescence of symptoms after the three first procedures, and their discharges commonly fail to show gonococci after the use of silver nitrate even though the gonococcus is present in the tissues. The safety of the patient and the protection of his possible contacts demand more careful tests of cure than these. In them the most careful and repeated searches of the washed sediments of the first urine voided following the aforementioned tests of cure should be carried out. Before such urine is voided the prostate, seminal vesicles and urethra should be stripped, so that their fluids are in the urine. Added to this, cultures for the gonococcus assume a place of enormous importance. And, no matter how carefully all these tests are carried out, some infected persons are almost sure to be passed back into sexual activity. Complement fixation tests are of little aid in the pronouncement of cure.

Because of the inferential character of all tests of cure, every patient should be warned against coitus without the use of a condom for some weeks after supposed cure.

OTHER TREATMENTS

An article such as this would be incomplete if no mention was made of biologic substance such as vaccines, filtrates and antitoxins, and prolonged hyperthermia. The biologic substances can be dismissed with the statement that, as a class, they have given about the poorest results of any seemingly sensible treatment.

Prolonged hyperthermia cannot be dismissed in so summary a fashion. That prolonged elevations of the body temperature above 106°F. will cure gonorrhoea in many cases is beyond question. That lower temperatures are less efficient and require more sessions of treatment also is established. It is equally certain that the method has dangers that are not to be viewed lightly and a mortality far greater than has the disease itself. The method requires equipment, trained personnel and time, which puts it out of the reach of the masses except, perhaps, when it is done experimentally. It is the opinion of Carpenter and Warren and their co-workers, who have done the most scientific work along these lines to date, that, in the male, it should be used for only those patients who resist cure by other methods and in the treatment of the graver complications of the disease. Such a view limits the urgent need for prolonged hyperthermia to a point where a physician has no cause to feel that

he is guilty of denying his patient the best because he does not urge it. Almost all cases of gonorrhoea in the male can be cured by other means and few of the complications, other than arthritis, are of such gravity or so resistant to treatment that they do not subside within a short time under less dangerous and less uncomfortable modes of attack.

Histaminase in the Treatment of Allergic Dermatoses

By L. C. GOLDBERG, M.D.

(From the *Journal of the American Medical Association*, Vol. CXV, 10th August, 1940, p. 429)

THE discovery by Best and McHenry of an enzyme which specifically inactivates histamine suggests its use in the treatment of allergic cutaneous disorders. It has been shown that there is a release of so-called H substance in the blood during allergic shock and that this H substance may be histamine. Innumerable writers have endeavoured to demonstrate the fact that histamine must be the trigger mechanism which prepares the skin for various reactions, particularly the so-called triple response of vasodilatation (streak), wheal exudative (oedema) and reflex nervous dilatation (flare), which is dermatographism or urticaria itself. If this fact is true, then the assumption that treatment of these allergic states with histaminase is well founded and worthy of an extended trial before being discarded as another false hope in the long list of attempts to combat the allergic dermatoses.

Histamine may be obtained from the liver, lungs, skin, and other body tissues in a pure form under aseptic conditions. It is preformed in the cell in a slightly inactive form and is readily released into the surrounding area. This release is not entirely dependent on the destruction of the cells but may occur when the cells receive stimulation of a certain intensity, and the magnitude of this stimulation is dependent on the allergic irritability of the individual cells. The fact that very little histamine is found in the urine after the intravenous injection of large amounts of the substance led Best and McHenry to study distribution, properties and action of the substance or system producing this inactivation.

Histamine inactivating material was first demonstrated in horse lung and subsequently in beef lung, liver and kidney. The kidneys, duodenum, jejunum and cæcum each inactivated the greatest amount of histamine, and the kidney was more active than any other tissue in inactivating histamine.

Histaminase is a compound of physiologic albuminoid substance obtained from the intestinal mucous membrane. It is a loose white powder which is stable and dissolves in water to a slightly opalescent fluid. This preparation is put up as a dry powder of 2 histamine detoxicating units and in tablets enterically coated of 5 units. The unit is the amount necessary to inactivate 1 mg. of histamine during twenty-hour hours' incubation at 37°C. in a phosphate buffer solution at a pH of 7. Chemically histaminase is diamineoxydase. The change produced in histamine during inactivation appears to be oxidative since it is inhibited by potassium cyanide, and under anaerobic conditions it is accelerated by oxygen. It is suggested that rupture of the imidazole nucleus occurs in the histamine or that a complex non-dialyzable compound is produced. Reduction of the imidazole value parallels the degree of inactivation of histamine.

Roth and Horton determined the normal response of gastric acidity to subcutaneous injection of histamine. Several days after the response had been accurately established, histaminase was introduced into the duodenum from twenty-five to thirty minutes before the subcutaneous injection of histamine. This practically abolished the rise of gastric acidity. Likewise subjects were immersed in water at 24°C., and the curve of their gastric acidity under such conditions was similar to that caused by histamine. As before, the introduction of histaminase abolished the rise in gastric acidity. In

similar fashion, when histaminase was injected intramuscularly thirty minutes before the usual subcutaneous injections of histamine, the rise in gastric acidity was abolished. This is physiologic evidence that histaminase administered to man will inhibit the action of histamine and contrary to the work of Atkinson and Ivy, although they injected their histaminase intravenously instead of introducing it directly into the duodenum.

Karady and Browne carried out experiments to determine what effect pretreatment with histaminase might have on histamine and anaphylactic shock in animals. They used thirty guinea-pigs. The jugular vein of twenty pigs was exposed under slight ether narcosis and 3 units of histaminase dissolved in 2 c.c. of physiologic solution of sodium chloride was injected. In fifteen minutes all thirty received 4 mg. of histamine dihydrochloride intra-abdominally. In from five to seven minutes all the non-treated animals were in histamine shock; seven died. Two of the pretreated animals died in thirty-five minutes; all the rest survived. Thirty guinea-pigs were sensitized with 3 c.c. of 50 per cent egg white subcutaneously. From two to three weeks later twenty guinea-pigs were injected with histaminase under the same conditions as previously described. After fifteen minutes all received 2 c.c. of 50 per cent egg white intra-abdominally. Four of ten animals of the control group died in from ten to fourteen minutes; all had symptoms of anaphylactic shock in four or five minutes. None of the pretreated group died.

Horton and Roth described a case of hypersensitivity to cold, which case they had followed since 1927. They concluded that urticaria produced by hypersensitivity to cold was due to an overabundance of histamine. They treated their patient with subcutaneous injections of 0.1 mg. of histamine dihydrochloride weekly in an effort to increase the patient's tolerance to histamine. The patient improved. Later they treated a similar case with histaminase, administering 67 units in four and one-half days. He too improved.

Gilbert and Goldman prepared bronchioles for microscopic examination. The size of the bronchiole was recorded by the use of camera lucida. The addition of 3 mg. of histamine acid phosphate usually resulted in complete closure of the bronchiolar lumen. The preparation was observed for about ten minutes in order to rule out spontaneous relaxation and then the test drug was added. Histaminase caused slight dilatation of histamine-poisoned bronchioles in three experiments and no effect in two. After twenty-four hours' incubation at 37°C. a mixture of histaminase and histamine caused marked contraction of normal bronchioles in four experiments. Their conclusions were that histaminase is unable to prevent the action of histamine on these preparations.

Foshay and Hagebusch believe that serum sickness with its urticarial manifestations is due to release of

histamine in the tissues and circulation consequent on the union of serum protein antigens and antibodies. Six of eight patients with serum sickness received complete relief from 5 units of histaminase given orally three times daily. Within thirty-six hours all these patients had relief from their intolerable pruritus, patchy erythema and urticaria. Twelve patients were treated twice daily with the injectable form. Within seventy-two hours none of the patients had any further symptoms. They expressed optimism for the prophylactic use of histaminase in the prevention of serum sickness and further stated that this method of treatment is the only rational, genuinely effective and safe remedy known for this distressing condition. Moldenschardt treated five patients who had cutaneous disorders with histaminase, two of whom had eczema, one Quincke's edema, one a moist erythema associated with marked pruritus and one serum sickness following diphtheria antitoxin injections. All responded and recovered within a short time. Adelsberger reported excellent results with histaminase treatment in three cases of allergic eczema on a nutritional basis and one case of light dermatitis. Hartmann stated that twenty-five patients with severe acne conglobata who had failed to respond to all types of medical treatment showed remarkable improvement after four or five injections of histaminase. In most of the twenty-five cases there existed some digestive disorder. Blecha treated twelve children who had allergic eczema with oral and intramuscular histaminase; five were completely cured, three greatly improved and the remainder were unaffected. Laymon and Cumming treated seventeen patients who had urticaria with histaminase and recorded the following results: 59 per cent cured, 12 per cent improved and 29 per cent unimproved; no definite improvement in eight cases of atopie dermatitis, and it was of no value in two cases of dermographism. Forman stated that this therapeutic agent offers a new and helpful approach to the treatment of urticaria, angioneurotic edema and atopie dermatitis. In his report of thirteen cases of urticaria, all but one showed improvement, two of three cases of atopie dermatitis showed improvement, two of four cases of contact dermatitis showed improvement and one case of pruritus was controlled by histaminase. Urbach reported the successful treatment with histaminase of a woman aged 31 with severe purpura; vitamin C had been tried without any beneficial results. He concluded that in this instance the purpura was due to a deficient detoxifying function of the intestine. Matras, in discussing this case, mentioned one of chronic urticaria which had not been benefited by injections of histaminase. Baker reported two cases of cold urticaria which responded to treatment with histaminase. The first patient had a severe generalized headache, palpitation and general tremulousness associated with the urticaria. These symptoms subsided with the onset of the localized

Treatment with histaminase

Diagnosis	Number of cases	Results	Comment
Twenty-five cases under oral treatment			
Papular urticaria ..	1	Clinically cured	Histaminase used alone.
Atopic dermatitis ..	3	Improved	Histaminase in conjunction with other therapy.
Dermographism ..	2	Unimproved	Histaminase used alone.
Allergic eczema ..	3	2 unimproved 1 improved	Histaminase in conjunction with other therapy.
Chronic urticaria ..	13	8 clinically cured 5 unimproved	Histaminase used alone.
Idiopathic pruritus ..	3	Slight improvement	Histaminase used alone.
Ten cases under injection treatment			
Chronic urticaria ..	10	All improved	Fever up to 102°F. after first injection, general malaise, pain at site of injection; mild rises in temperature after second and third injections; very little thereafter.

œdema. Histaminase tablets were used simultaneously with gradual desensitization to cold. The results of the treatment were most gratifying. The second patient was treated similarly with the same good results. Kile and Rusk treated a patient who had cold urticaria with histaminase without any results. They did not mention the amount used or the length of time it was tried. Miller and Piness treated forty-two patients with histaminase; twenty-nine had urticaria, and only five were relieved; five had allergic dermatitis, and none were relieved. They felt that in no instance could this relief be unequivocably attributed to the use of the enzyme. They reported few untoward reactions.

The histamine-histaminase reaction is an oxidative one, and as yet I have observed no untoward reactions. There is no need to worry about the type of reactions that occur when a patient is treated with small doses of histamine such as flushing of the face, shivering or faintness, fall in blood pressure, rise in pulse rate, headache, anginal pains in the chest or shock.

My purpose in this paper is to picture the results of treatment of various allergic cutaneous disorders with histaminase, orally and by injection, and to demonstrate that it might be a valuable adjunct in the management of these cases. All the cases studied were taken from private practice and analysed from the clinical point of view. In some of them histaminase was used by itself while in others it was a part of the advised therapy. When it was not the only therapeutic agent, the patients had been rebellious to other routine treatment measures. Twenty-five patients received histaminase by mouth; these may be subdivided as follows: thirteen had recurrent urticaria, three allergic eczema, one papular urticaria, two dermographism, three atopie dermatitis, and three pruritus. Ten patients with recurrent urticaria received intramuscular injections of histaminase 2 c.c. every other day for a minimum of six injections and a maximum of twelve. The initial reactions of fever, malaise and joint pains following intramuscular injections of histaminase in 2 c.c. doses suggest the possibility of a foreign protein reaction. However, the same type of reaction does not always, occur after the second or third injection, which does not hold true for reactions following injections of whole milk and other non-specific proteins. This requires further investigation of the injectable material. All the patients so treated showed marked improvement, and after treatment was discontinued no recurrences have been noted up to the present time.

SUMMARY

This group of thirty-five cases is too small a series to permit any dogmatic statements. In several cases the use of histaminase alleviated all the symptoms while in others it was a very useful factor in controlling the pruritus. Histaminase is no more a cure-all for allergic cutaneous conditions than are allergens the sole major excitants in the same diseases. Furthermore, it must be remembered that histaminase is a protein preparation and probably contains a variety of proteins which might cause reactions in patients whose allergy is of a protein type. It is possible that treatment with histaminase may give the epidermal structures relief from histamine excitation and help it build tolerance to histamine in the same way that intravenous injections with histamine in the treatment of chronic urticaria produces a gradual unresponsiveness of the skin to 'H substance', which is thought to be responsible for whealing, as believed by Alexander. I know that there has been no established fact that histamine is the causative agent in any pathologic condition and that most of the present data may be presumptive. Nevertheless evidence has been presented showing that histaminase oxidizes histamine in the body and on this basis its therapeutic assistance in the treatment of allergic dermatoses may be justifiable.

CONCLUSION

Histaminase oxidizes histamine in the body and is a helpful factor in the treatment of allergic dermatoses. A small group of thirty-five patients with various allergic dermatoses was treated with histaminase, orally

and by injection. There was partial or total improvement noted in all but nine of the patients treated. I can draw no definite conclusions regarding the dosage of histaminase, since each case must be studied individually. However, as yet no untoward reactions have been noted after patients have taken as much as 150 histamine detoxicating units daily for four or five days. Patients receiving intramuscular injections of histaminase had very much better results than those receiving the enzyme in tablet form. The first four injections elicited symptoms comparable to those following foreign protein shock therapy. Further clinical and laboratory data are necessary before any definite conclusions can be drawn regarding the specific value of histaminase.

The Therapeutic Use of Sulphathiazole

(From *International Medical Digest*, Vol. XXVII, December 1940, p. 373)

SINCE prontosil initiated the era of chemotherapy, of which Paul Ehrlich dreamed 40 years ago, each new member of the sulphanilamide group has been enthusiastically received. This has been largely due to the amazing results which have been obtained from the earliest days as well as the almost unbelievable successes attained with each new preparation shortly after its appearance. Sulphathiazole, an analogue of sulphapyridine, is the latest of this group. Its predecessor, sulphamethylthiazole, introduced chiefly to combat staphylococcus infections, was soon abandoned, after its release from the experimental laboratory, because of serious reactions, which have been overcome to a large extent by the introduction of sulphathiazole.

Pharmacology.—Chemically, sulphathiazole (2-sulphanilylaminothiazole) is closely related to sulphanilamide and sulphapyridine. Its empiric formula is $C_6H_5N_2O_2S$, and its molecular weight is 255. The melting point is 200°F. and its taste is slightly sweet. It is poorly soluble in cold water, more soluble in hot water, but easily soluble in alkalies and alkaline earths with the formation of salts, such as the sodium salt, which is stable in concentrations up to 20 per cent. Apparently, sulphathiazole is most effective when a concentration of 3 to 6 mgm. per 100 c.c.m. of blood is maintained. This may be accomplished one hour after the oral administration of a single dose of sulphathiazole, when a blood level of 4.5 mgm. per 100 c.c.m. of blood is reached. Such a level remains optimally for four to six hours, and as a consequence it is desirable to administer it at four-hour intervals. Absorption of the drug from the intestinal tract is apparently satisfactory, but it does not pass readily into the spinal fluid. For this reason, it should not be relied upon in the treatment of any infection of the meninges.

Following its intravenous administration, it is easily recovered in the urine and practically all of it is eliminated within 24 hours. This is an additional reason why its administration at 4-hour intervals is desirable if we expect to obtain and maintain an optimal blood concentration of 4.5 mgm. per 100 c.c.m. of blood. The urinary output of sulphathiazole is, however, not as great as sulphapyridine, so that the concentration in the urine might be higher. It therefore becomes important to maintain an adequate fluid output by administering sufficient fluids during its use.

Toxicity.—It is too early to know all of the contraindications and side-effects of sulphathiazole. It would therefore seem desirable to proceed cautiously in any patients who have previously suffered a toxic reaction in the course of therapy with sulphanilamide or sulphapyridine. Furthermore, the indiscriminate use of sulphathiazole in comparatively insignificant infections should be avoided.

So far, *nausea* and *vomiting* have been less frequent and milder than with sulphapyridine, and usually subside even with continued administration. These two symptoms have been rarely severe enough to necessitate discontinuing the administration of sulphathiazole. Other toxic effects are *vertigo*, *headache*, and *malaise*, but it is questionable as to whether these are due to

the drug or the infection which is being treated. *Hæmaturia* may sometimes be persistent between the first and tenth days, and when it occurs, it has been construed as an indication to stop the drug and force fluids. Because of this urinary manifestation, dehydration should be avoided by giving sufficient fluids to maintain the daily urine output at about 1,500 c.c.m.

It is quite generally conceded that patients with severe grades of anaemia or low white blood cell counts have been treated with sulphathiazole without deleterious effect on either the red or white blood cell count. *Acute leukopenia with granulocytopenia* has been reported as occurring between the third and tenth days. It is therefore desirable to make daily blood counts during the course of treatment with this drug, and when there is an acute decline in the white cell count, with granulocytopenia, it is imperative that the drug be stopped immediately and that fluids be forced.

It is desirable to be alert to the fact that sulphathiazole may cause *injury to nerve tissues*. Symptoms attributable to nerve injury are less frequent since sulphathiazole has replaced sulphamethylthiazole. However, all early manifestations of *paresthesia, interference with muscular contraction, or pains of a neuritic nature* call for immediate discontinuance of the drug.

Until more is known concerning toxic reactions, the administration of sulphathiazole should be discontinued just as soon as improvement in the patient's condition appears.

Indications.—So far, sulphathiazole is indicated chiefly in *staphylococcus infections*, and the results obtained have been as striking as in streptococcal infections when sulphanilamide is used. The use of the drug, however, in several thousand cases of *pneumococcus pneumonia* revealed results which closely parallel those obtained with sulphapyridine. In addition, beneficial effects have been recorded in both *pneumococcal and staphylococcal infections of the ear, nose and throat, urinary infections, colon-typhoid dysentery infection, and in hæmolytic and non-hæmolytic enterococcal infections*.

The chief use of the drug, however, seems to be in *pneumococcus pneumonia* and *staphylococcus infections*. The following procedures which have been compiled by Ciba Pharmaceutical Products, Inc., of Lafayette Park, Summit, New Jersey, one of the pharmaceutical houses through which sulphathiazole is available, serve as an excellent guide for the use of sulphathiazole in both of these conditions.

Procedure in pneumonia.—Before administering sulphathiazole:

1. Obtain a sputum sample for typing, directly or by mouse inoculation.
2. Take a blood culture to determine the presence of a bacteraemia.
3. Do a red and white blood cell count, a haemoglobin determination, and a differential white cell count and urine examination.

Dosage.—The clinical acumen of the physician and the progress of the patient, and the laboratory procedures should be the ultimate guides for the dosage of sulphathiazole. Experience, however, dictates the following procedure:

1. Administer the drug early.
2. Raise the blood plasma level of sulphathiazole in a rapid manner by the administration of a relatively large amount of the drug within a short space of time.
3. Maintain a blood level of 3 to 6 mgm. per 100 c.c.m. of blood of the non-conjugated sulphathiazole. (Acetyl sulphathiazole is inactive)

To accomplish the above, the following schedule for individuals over age 15 is suggested:

1. Initial dose of 4 gm. (8 tablets).
2. After 4 hours and at 4-hour intervals, 1 gm. (2 tablets) night and day until the temperature has fallen by crisis or lysis and remains normal for 48 hours.
3. One gm. (2 tablets) every 6 hours for the next 24 hours.
4. If temperature, pulse and respiration remain normal, discontinue the drug at the end of this period.

It is self-evident that the dosage in very old or debilitated patients has to be adapted accordingly by decreasing the dosage customary for the adult.

In infants and children, a dose of 1 gm. (2 tablets) per 15 pounds of body-weight up to 50 pounds, should be administered (0.15 gm./kg.). The accompanying table may be used as a guide to dosage.

Sulphathiazole and serum.—Specific horse or rabbit serum therapy together with sulphathiazole may be advisable in certain conditions:

1. If pneumococcal bacteriæmia is present.
2. If a patient is over 40 years of age.
3. If treatment has not been started until after the third day of infection.
4. If two or more lobes are involved.
5. If other complications are present.
6. If the pneumococcal infection is of type 1, 2, 5, 7, 8, or 14.

Age	Approximate weight	Initial dose per os		Maintenance dose per os q. 4 h. (Day and night)	
		Years	Pounds	Gm.	Tab.
5	40		2.5	5	0.5
2	28		2.0	4	0.375
1	21		1.25	2½	0.25
½	15		1.0	2	0.165
¼	12		0.75	1½	0.125

Staphylococcus infections.—Sulphathiazole should not be used in the treatment of minor staphylococcal infections such as localized boils and small carbuncles or in mild furunculosis. Furthermore, sulphathiazole should not be used in place of surgery. It should be used as an adjuvant to surgery. In large boils or carbuncles, with accompanying toxic symptoms, follow the same dosage as in pneumonia. In diffuse staphylococcal cellulitis, lymphangitis, or acute osteomyelitis, give dosage as follows:

1. Initial dose of 4 gm. (8 tablets).
2. After 4 hours 1.5 gm. (3 tablets) every 4 hours night and day until the spread of infection appears to be under control.
3. Then 1 gm. (2 tablets) every 4 hours night and day and continue as indicated.

In staphylococcal bacteriæmia, prolonged treatment with sulphathiazole is indicated in order to prevent a relapse. Give:

1. Initial dose of 4 gm. (8 tablets).
2. After 4 hours 1½ gm. (3 tablets) every 4 hours day and night until temperature has been normal for 48 hours.
3. Then 1 gm. (2 tablets) every 4 hours day and night for 14 days.
4. Then 0.5 gm. (1 tablet) every 4 hours night and day for at least another 14 days.

The daily dosage in children in these infections is to be calculated on the basis of 1 gm. (2 tablets) per 12 pounds (note: not 15 pounds as above) of body-weight (up to 45 pounds). The suggested schedule for these children is as follows:

1. Initial dose 1 gm. (2 tablets) per 12 pounds body-weight.
2. After 4 hours the initial dose becomes the daily dose which is divided into six parts and is thus given at 4-hour intervals day and night until the temperature has been normal for 48 hours.
3. Reduce dose by one-third and continue for 14 days.
4. At this time reduce dose by one-half and continue according to clinical needs.

Reviews

LECTURES ON DISEASES OF CHILDREN.—By Sir Robert Hutchison, Bart., M.D., LL.D., F.R.C.P., and Alan Moncrieff, M.D., F.R.C.P. Eighth Edition. 1940. Edward Arnold and Company, London. Pp. viii plus 471, with 107 Illustrations. Price, 21s.

THE fate of medical 'classics' would be a very interesting study. In many instances it would be better if they disappeared with their original authors from the medical stage, and made room for new books by writers of the younger generation. A compromise is possibly the best solution. How this compromise can be effected is exemplified in the book under review. Sir Robert Hutchison, president of the Royal College of Physicians, has certainly not yet retired from the medical stage but he has relegated the work of rewriting one of his 'classics' to a junior colleague, whilst he is still capable of exerting his influence on the teaching contained therein, not solely by virtue of his past experience. This ensures continuity of the spirit of the teaching, even when the letter has to be changed.

The title of the book is particularly appropriate; the chapters are lectures in more than name. One can visualize Robert Hutchison lecturing and see his movements and expressions. Perhaps younger readers can visualize Alan Moncrieff in the same way; we have not had the privilege of hearing him lecture. The book is one of the most readable we know. It is arranged for reading rather than for reference, but reference is facilitated by the judicious use of heavy type.

The lectures themselves deal with all subjects connected with the health and the diseases of children, but emphasis is laid on the simple and every-day ailments, rather than on the rare diseases. The fact that no attempt is made to deal with tropical disease is, in our opinion, evidence of the honesty of the writer. The book is well and appropriately illustrated, the page pleasantly readable, and the volume a handy one. We can recommend this book very strongly to the general practitioner.

CHEMOTHERAPY AND SERUM THERAPY OF PNEUMONIA.—By Frederick T. Lord, M.D., Elliott S. Robinson, M.D., Ph.D., and Roderick Heffron, M.D. 1940. The Commonwealth Fund, New York. Pp. ix plus 174. Illustrated. Price, \$1.00. Obtainable from Oxford University Press, Bombay and Calcutta

This handbook on pneumonia deals with the clinical features and diagnosis of pneumonia and its treatment by chemotherapy and serum therapy.

The book is divided into fifteen chapters. The first six chapters discuss the problem of pneumonia, the clinical features, methods of diagnosis—clinical and bacteriological, immunity factors in pneumonia, and the prognosis. The rest are devoted to a full discussion of chemotherapy and serum therapy, the details of mode of administration, indications, contra-indications, toxic effects and dangers of each type of therapy, and the results obtained by each separately and when administered together. Mass statistics collected from different parts of the world (the figures include those of two articles published in this journal in 1939) have been presented to show that the gross mortality of sulphapyridine therapy is 6.1 per cent, while with serum therapy the mortality was 12.5 per cent in type I and 20.5 per cent in type II pneumococcal pneumonia in America, where elaborate arrangements for serum therapy of pneumonia were made. In control cases, the fatality rate was about 25 per cent according to very conservative estimates. While the writers agree that chemotherapy yields much better results, they have emphasized the dangers of toxic effects to such an extent and have advised the adoption of so many bacteriological, biochemical, and haematological

examinations to prevent these, that this may discourage the general practitioner from using one of the most potent remedies against pneumonia. The reviewer fully agrees that the recommendations are scientific, but such elaborate laboratory facilities are not available in most parts of the world, and it will be a real tragedy if the general practitioner apprehensive of serious toxic effects, the risk of which is undoubtedly very small, should hesitate to treat any of his pneumonia cases by adequate dosage of sulphapyridine.

The book is a mine of information regarding modern methods of diagnosis and treatment of pneumonia, and as such will be found to be extremely useful by the medical profession.

P. C. S. G.

THE HUMAN MIND: THE ORGAN OF THOUGHT IN FUNCTION AND DYSFUNCTION.—By Murdo MacKenzie, M.D., M.R.C.P. 1941. J. and A. Churchill, Limited, London. Pp. vii plus 216. Price, 7s. 6d.

This is a very strange book. On page 37 we find the following statement: 'The reactions of Simplification are best described as Assertion on the one hand, and Depression on the other; qualifying Assertion by Immediacy, and Depression by Deliberation. The neuroses of Simplification are, then, Assertion and Depression; and the symptoms of Assertion are often experienced in clinical practice'. Admittedly it is a little unfair to take the above out of its context but even read with the context, it evokes in the reader's mind a sensation like that caused by the noise of clashing bells or the breaking of glass. One reads on, bewildered. In the last chapter the author brings his psychological technique to bear on the present war. We are informed that Nazi propaganda is the propaganda of a 'perverted Immediacy' in defence, and that 'its effect on the stable deliberate is inappreciable; much of it is rejected as absurd, and the rest as fatuous fussiness. But in a deliberate already the prey of persisting conflict, the effect of raising the intensity of the moment is to increase his pre-existing Anxiety', and so on. As a specimen of therapeutic procedure recommended by the author for combating mental dysfunction the following may be cited: 'The patient is first asked to look at the match-box on the consulting-room desk: the match-box is then removed, and he is asked to make a visual image of it and discuss matches, wood and any other chance association'. The simplicity of such procedure is commendable, but its therapeutic value is difficult to apprehend without some explanation but none is given.

O. B-H.

THE THEORY OF OCCUPATIONAL THERAPY FOR STUDENTS AND NURSES.—By Norah A. Haworth, M.A. (Cantab.), M.R.C.S., L.R.C.P., D.P.M., and E. Mary Macdonald. 1940. Ballière, Tindall and Cox, London. Pp. ix plus 132, with 81 Illustrations. Price, 6s.

In his foreword to this little book Sir Robert Stanton Woods very rightly calls attention to the fact that occupational therapy, in spite of being one of the oldest agents employed in psychotherapy (first introduced into English mental hospitals by Sir William Ellis in 1817), has only quite recently gained widespread recognition. Even now, its value is either not recognized or actively opposed in many general hospitals. In tuberculosis sanatoria and in the surgical wards of general hospitals, the employment of occupational therapy makes slow progress except in the United States. Sir Robert Stanton Woods is quite justified in describing this state of affairs as 'a grave reflection upon the medical profession'. In such circumstances this book on the theory and practice of occupational therapy should find a place in every up-to-date hospital. The authors discuss the subject from the standpoint of psychotherapy as well as from that of physiotherapy; the latter including orthopaedic and surgical

cases. There is an admirable exposition on the finance, equipment stocking, storage, and use of waste materials. This section of the book should be studied first by anyone who intends to introduce occupational therapy into a hospital or sanatorium. The term occupational 'therapist' is used throughout the book, although etymologically the correct term to employ is 'therapeutist'.

O. B-H.

THE EARLY TREATMENT OF NERVOUS AND MENTAL DISORDERS.—By W. Lindesay Neustatter, B.Sc., M.B., B.S., M.R.C.P. (Lond.). 1940. J. and A. Churchill, Limited, London. Pp. xii plus 379. Price, 15s.

In the 370 pages of this book the author sets forth an amazing amount of information. In the preface he states he has tried to write a book which will be of value to the general practitioner, the psychotherapist and the mental hospital psychiatrist. A commendable ambition! By far the most interesting and important part of the book is that devoted to the mental disorders of children and their treatment. It repays the closest study and will be found of great value not only to psychotherapists but to parents, teachers and social workers. The author recommends that 'mental hygiene' should concern itself solely with sexual hygiene. There is a great deal to be said for this, in view of the widespread existence of complete ignorance on sex and all that this term connotes. Dr. Neustatter appears to hold the belief that homosexual men and women seek treatment for their disability. If his opinion is based on his experience, one is forced to conclude that his experience has been very exceptional. Indian readers of this book who take an interest in psychotherapy will be saddened by the reflection of how very little is being done in this country as compared to what is being done for psychological medicine in Europe and the United States of America.

EMERGENCY SURGERY.—By Hamilton Bailey, F.R.C.S. (Eng.). Fourth Edition. 1940. John Wright and Sons, Limited, Bristol. Pp. x plus 944, with 930 illustrations, of which a large number are in colour. Price, 63s.

THIS book is becoming an annual issue; the third edition appeared in 1938, it was reprinted in 1939, and the fourth edition appeared late in 1940. The important advances made during the last two years in many branches of surgery is the reason given for the publication of another edition, but a more material one was probably the exhaustion of the last edition and the certain demand for the book during these times of emergency.

For the benefit of those who are not familiar with this new world-famous book, we will quote from the preface—"when to operate, when not to operate, and how to operate under emergency conditions is the theme of this work". If one has a criticism of this excellent book, it is that the emergency visualized is usually one of time rather than of place and equipment.

The changes in the present edition are numerous but they are not very prominent, and, should any prospective reader imagine that emergencies of everyday life have been sacrificed to war emergencies, we will relieve his mind by telling him that they have not; in fact no chapters have been devoted particularly to war wounds or air raid casualties, but the special emergencies that are likely to arise in these connections are dealt with in their appropriate sections. Beyond the written word, there is not the slightest sign of the war in this book, for the paper on which it is printed is of the same excellent quality usually used by the publishers of the *Journal of Surgery* and the illustrations are of the same superb quality. To produce such a book in war time reflects great credit on British character, and Britain's resources.

PYE'S SURGICAL HANDICRAFT: A MANUAL OF SURGICAL MANIPULATIONS, MINOR SURGERY, AND OTHER MATTERS CONNECTED WITH THE WORK OF HOUSE SURGEONS AND OF SURGICAL DRESSERS.—Edited by Hamilton Bailey, F.R.C.S. (Eng.). Twelfth Edition. 1940. John Wright and Sons, Limited, Bristol. Pp. xii plus 595, with frontispiece and 482 illustrations. Price, 21s.

WALKER Pye died nearly fifty years ago, but his spirit lives on in the world-famous book that bears his name. There can be little more than the spirit of his teaching left in the present edition, for the book is essentially devoted to descriptions of the use of 'gadgets', and mostly modern 'gadgets' to use a popular word. The writers prefer the word armamentarium, a word they have filched from the physician, who we feel will not resent the 'protection' that these surgeons are prepared to offer it.

The instruments whose uses are described range from the hypodermic syringe to the cystoscope; the minor surgical procedures include the opening or tapping of abscesses in almost all parts of the body (except the liver—an omission which might well be rectified in a subsequent edition); the treatments of burns, fractures and dislocations are detailed: the preparation of the patient for an operation and his after-care is given; and in fact this book includes almost all information on matters of technique that the house surgeon or the general practitioner can want.

Mr. Hamilton Bailey has mobilized a representative army of contributors, most of whom write obviously from personal experience. The descriptions of spleen and sternal puncture appear to be exceptions and suggest that the writer has taken these from other textbooks; we cannot believe that the statement, copied from text-book to text-book, that a hammer is usually required to drive in a sternal puncture needle can have any basis in practical experience.

However, the descriptions on the whole are excellent—well chosen, explicit and concise. The house surgeon will find it an invaluable aid in almost any procedure which he may be asked to undertake.

THE HEAD AND NECK IN ROENTGEN DIAGNOSIS.—By H. K. Pancoast, M.D., E. P. Pendergrass, M.D., and J. Parsons Schaeffer, M.D., Ph.D. 1940. Ballière, Tindall and Cox, London. Pp. xxxii plus 976, with 1,251 illustrations. Price, 69s.

THIS is a large book of over 1000 pages profusely illustrated by reproductions of skiagrams, anatomical drawings and diagrams.

As stated in the authors' preface the aim of the book is to correlate the basic and technical aspects of radiology with apposite facts in developmental and adult morphology, physiology, pathology, and observations in clinical medicine and surgery and the special branches of the last-named sciences.

This is a comprehensive undertaking. How well the authors have succeeded will be apparent only to those who have the need and the opportunity of consulting the mass of facts collected herein.

Detailed considerations of descriptive and physiological anatomy have been omitted and only those aspects which especially concern the radiologist are included.

In this way, and by careful selection of the matter available, as well as curtailment of unnecessary descriptions and discussions, the book has been limited to a single volume.

It is essentially a work of reference and as such should find a place on the shelves of practising radiologists and specialists in ophthalmic and nose and throat work.

The authors and publishers are to be congratulated on the presentation of the text and illustrations.

ANATOMY (HEAD AND NECK). PART III. Fifth Edition. Catechism Series. By C. R. Whittaker, F.R.C.S.E., F.R.S.E. E. and S. Livingstone, Edinburgh. Pp. 74. Price, 1s. 6d.; postage, 2d.

THIS booklet is not new being a well-known member of the 'Catechism' series. In passing through four editions it has served the needs of many students, especially before the examinations, by enabling them to revise the whole text quickly yet without having to miss any of the important anatomical facts. The present edition, it is also hoped, will be serviceable to the same extent. The essential facts of the region have been very neatly compressed to the present size, very suitable for revision purposes, in the leisure hours in between long and detailed study of the voluminous text-books, which being presented in the form of answers to questions under each heading has acquired an added value.

While this book, along with others of the series, has, no doubt, considerable utility, we feel it very necessary to emphasize to those for whom it is meant that such works are never intended to replace the study of the main textbooks, but only to serve as a dependable compendium for recapitulation of the main and important structures, already read in the usual course of studies from textbooks. If therefore the book is used as is its designed purpose, there is hardly any to surpass it.

As to contents it is seen that the larynx is not included in part III (Head and Neck), but although the other parts are not before us, the larynx should, in our opinion, be included in the region of the head and neck.

S. C. S.

SYPHILIS IN EARLIER DAYS.—By J. R. Whitwell, M.B., 1940. H. K. Lewis and Company, Limited, London. Pp. viii plus 89. Price, 6s.

In this small volume the writer has presented extensive quotations from old literature, purporting to show the presence of a disease, the description of which is *very similar* to that of syphilis. The author's contention is that these writings show the presence of syphilis in different parts of the world centuries before

the sailors of Columbus returned to Europe from their voyage to America and were supposed to have brought syphilis to the old world. Those interested in the history of syphilis will find the book useful.

P. C. S. G.

ORGANIZATION, STRATEGY AND TACTICS OF THE ARMY MEDICAL SERVICES IN WAR.—By Lieut.-Colonel T. B. Nicholls, M.B., Ch.B. Second Edition, 1940. Ballière, Tindall and Cox, London. Pp. xvi plus 488. Price, 15s.

THIS is a book of the moment—or, should one say, an edition of the moment, for the first edition was published three years ago and was very well received. There are at the present time a large number of temporary officers in the Royal Army Medical Corps and Indian Medical Service who are preparing themselves for service in war areas. Many of them are probably feeling that they are wasting much valuable time and want to get on with the job, but that is always the way; very fortunately *all* the medical services are not busy *all* the time, and, during the waiting months, the inexperienced have an excellent opportunity to learn; they will find Colonel Nicholls' book a very valuable source of information.

The book is of course an elaboration of army manuals, but there is much additional information, and one is conscious of the touch of personal experience.

The book is divided into four main parts, on general organization and administration, the composition of medical units, and special organization, medical tactics and strategy, and a selection of exercises in medical strategy.

The new matter added in this edition includes the transport of casualties by air, medical services in connection with anti-aircraft work, and co-operation with civil emergency medical services.

The author has recruited a number of collaborators particularly for the new matter in which he lacks personal experience, so that the whole book is based on practical experience.

It is, as we said at the beginning of this review, a book of the moment.

Abstracts from Reports

ANNUAL REPORT ON THE WORKING OF THE CIVIL HOSPITALS AND DISPENSARIES IN THE MADRAS PRESIDENCY FOR THE YEAR 1939

Number of hospitals and dispensaries.—At the commencement of the year there were 1,322 medical institutions of all classes in this Presidency as against 1,325 at the end of the year 1939.

The number of in-door and out-door patients treated in the State public, local fund, private aided and subsidized rural dispensaries.—**Beds.**—The total number of beds that were available in all classes of medical institutions for both the sexes in the year 1939 was 7,030 and 5,930 as compared with 6,856 and 5,590 in 1938. The total number of beds for women alone in these hospitals was 1,696 in 1939 as against 1,496 in 1938.

In-patients.—The number of in-door patients treated during the year 1939 was 342,811 as compared to 310,030 in the previous year.

Out-patients.—The total number of out-door patients treated in all the hospitals and dispensaries in the Presidency during the year 1939 was 19,499,555 as compared to 18,692,411 in 1938.

Daily average.—The daily average number of inpatients treated during the year 1939 was 14,600.03 as compared to 13,820.64 in 1938. The daily average number of out-door patients treated in the medical

institutions during the year 1939 was 142,199.03 as against 132,894.43 in 1938.

Among the various diseases treated in all classes of hospitals and dispensaries those that accounted for the largest number are shown below:

Other diseases of the eye	1,439,157
Diseases of the ear	1,203,940
Ulcerative inflammation	1,411,073
Other diseases of the skin and nails excluding tumours	1,007,344
Injuries (general and local)	1,222,331
Diseases of the respiratory system other than pneumonia and tuberculosis ..	1,491,515
Other diseases of the digestive system excluding diarrhoea, dysentery and tumours	1,364,793

Malaria.—The total number of patients treated during the year under report was 1,111,024 with 371 deaths as compared to 1,276,658 with 386 deaths in the previous year.

Dysentery.—The number of patients, both amœbic and bacillary dysentery, treated during the year 1939 was 381,605 with 643 deaths as compared to 327,497 with 548 deaths in 1938.

Enteric fever.—The number of patients treated during the year under report was 26,013 with 902 deaths as compared to 24,290 with 726 deaths in the previous year.

The Value of Dietary Supplements

A Summary of Investigations published in the "Medical Officer," March 30 and April 6, 1935*

A NUMBER of children, all receiving their customary home diet, were given either No Supplement, Cod Liver Oil, Halibut Liver Oil (with milk to provide equal calories) or Virol. The experimental scheme provided that each child should have a period on each treatment in turn, in such a way that every possible sequence was included. Rigid statistical control was thus possible.

Gain or Loss in Weight on Various Supplements :—

Supplement	Total gain in ozs. over all periods	Average gain per child per week in ozs. over all periods	Total loss in ozs. during summer period only	Average loss per child per week in ozs. during summer period only
No Supplement - - -	88	0.3	— 103	— 1.4
Cod Liver Oil - - -	287	1.0	— 77	— 1.1
Halibut Liver Oil with milk - - -	333	1.2	— 184	— 2.6
VIROL - - - -	762	2.6	— 7	— 0.1

Whereas earlier investigations had shown that the mere addition of vitamins had no effect on growth, these investigations have conclusively proved that Virol—a balanced food containing all the necessary vitamins—has a definite and remarkable effect in bringing the rate of growth up to the recommended standard. Virol was the only one of the supplements used that promoted this ideal rate of growth.

Virol was the one and only preparation that maintained the children's weight in the hot weather.

* The full report will be sent on application to Messrs. A. H. Wheeler & Co., Sudama House, Wittet Road, Ballard Estate, Bombay.

TO CLEAN FALSE TEETH

Convenient and Easy to Use

'Steradent' is a modern scientific preparation for cleaning false teeth. The Dental Profession has endorsed the opinion that 'Steradent' cleans and purifies dentures as nothing else has ever done before. It is harmless to denture materials. It contains no free chlorine or acids. It is alkaline in action. Mucin film, tartar, stains, tarnish and all unsanitary accumulations are removed. Patients should immerse their dentures overnight in warm water in which Steradent powder has been dissolved.

APRIL, 1941]

ABSTRACTS FROM REPORTS

Kala-azar.—The total number of patients treated in 1939 was 1,697 with 18 deaths as against 2,263 with 20 deaths in 1938.

Labour cases.—During the year under report 127,318 labour cases were conducted in all classes of medical institutions of which 107,743 were normal and 19,575 abnormal as against 123,381 labour cases consisting of 104,244 normal and 19,137 abnormal cases during the previous year.

Rural medical relief.—The new scheme of training rural medical practitioners for the performance of public health work progressed satisfactorily during the year under review.

To avoid the overlapping of medical relief, Government have ordered the stoppage of payment of contributions by local bodies to private practitioners who have settled within five miles radius from a rural dispensary.

Tuberculosis.—In order to combat tuberculosis, the Madras Provincial Tuberculosis Association, with its various committees, was constituted and affiliated to the All-India Tuberculosis Association. The Association is making plans for opening clinics in all Headquarters Hospitals for the diagnosis and the treatment of patients in the initial stage. The proposal relating to the transfer of the Tuberculosis Hospital in Madras to the Sanatorium at Tambaram and to develop it so as to have a well-equipped unit on modern lines has been approved and a beginning made but for financial reasons it may be some time before the transfer is completed.

During the year under review a post-graduate course of lectures on tuberculosis was held at Madras and Madahapalle under the auspices of the Tuberculosis Association of India, and 24 candidates attended the course.

Anti-leprosy campaign.—During 1939 the British Empire Leprosy Relief Association established its headquarters at the Lady Willingdon Leper Settlement, Chingleput. The control over certain specialized clinics was handed over to the association.

The work done during the year under report is as follows:—

Investigation into the causes of various types of leprosy and the factors which led to their development among children is being conducted at Saidapet. The rural investigation unit has been continuing to do active work. Investigations are being pursued on the study of various types of diseases and influence of diet on the course of development at the Lady Willingdon Leper Settlement, Tirumani. Preliminary surveys by the Urban Investigation Unit have been carried out with the co-operation of the Madras Branch of the Provincial Council of the British Empire Leprosy Relief Association.

Building schemes.—During the year the following medical buildings were completed or nearly completed:—

- (1) A septic ward of 52 beds in the Government Rayapuram Hospital, Madras.
- (2) An additional ward of 88 beds in the Government Victoria Caste and Gosha Hospital, Madras.
- (3) Additional blocks in the Government Mental Hospital, Madras.
- (4) An additional ward of 18 beds in the Government Tuberculosis Sanatorium at Tambaram.
- (5) A new out-patient block in the King George Hospital, Vizagapatam.
- (6) The new Headquarters Hospital, Cocanada.
- (7) The new Headquarters Hospital, Madura.
- (8) The buildings connected with the remodelling scheme of the Government General Hospital, Madras.

Sanction has also been accorded for the construction of a maternity and children's ward and an extension to the Pathology Block of the King George Hospital, Vizagapatam.

Medical education.—Consequent on the establishment of a second Medical College in the Madras City, a

central institute of Anatomy and Physiology including Organic Chemistry and Biochemistry was organized from January 1939 at the Madras Medical College, so that the students of the Madras and Stanley Medical Colleges might be taught in one place. A course for the B.Sc. degree in Pharmacy was instituted in the Madras Medical College from July 1939. The record of the work of the medical educational institutions continued to be satisfactory.

The training of candidates for the diploma course in medical radiology and for the certified Radiological Assistants' course was started during the year under review. The M.B.B.S. degree of the Andhra University has been granted temporary recognition by the Medical Council of India for a period of two years from 1st December, 1938.

Honorary medical system.—The replacing of salaried medical officers by honorary medical officers was carried on during the year. Fifteen posts of Civil Assistant Surgeons in the city and the mofussil were filled by honorary medical officers. Orders were issued throwing open a large number of paid posts of Civil Assistant Surgeons and Sub-Assistant Surgeons in hospitals to honorary medical officers. The intention was that these posts should be filled by honorary medical officers as vacancies arise. A certain number of supernumerary posts for honorary medical officers were also filled. The Government have recently consulted all the recognized medical bodies in the Province on the honorary system and the question of modifying the scheme is under consideration.

General.—The work of medical-relief in this Province has shown marked improvement during the period under report. The number of hospitals and dispensaries has increased and the number of beds has also correspondingly increased. It is gratifying to note the increase in the daily average attendance of in- and out-patients which indicates the popularity of the allopathic medical institutions. The expansion of the x-ray facilities has given more impetus for the correct diagnosis and efficient treatment to patients.

ANNUAL REPORT AND STATISTICS OF THE KING GEORGE HOSPITAL, VIZAGAPATAM. FOR THE YEAR 1937

EIGHT cases of pellagra were admitted during the year.

During the year 34 cases of rheumatic infection were admitted. Nine were of acute rheumatic fever with polyarthritis and no cardiac involvement. The remaining 25 cases showed cardiac involvement; of these 10 were males, 12 females and 3 children. Of the 10 males, one had aortic regurgitation in addition to mitral disease. Of the 12 females, 3 cases were of pure mitral stenosis; 3 showed both mitral and aortic disease; the 3 children had rheumatic carditis. There was one case of chorea admitted on the female side.

Six cases of beri-beri were admitted and some of them were treated with a full course of Betaxin with marked improvement.

A case of particular interest was one of endothelioma of the pleura, which was admitted with pleural effusion which was found to be haemorrhagic; on investigating the cause of this haemorrhagic effusion, it was found to be due to endothelioma of the pleura.

The following is a brief account of interesting cases that have been admitted and treated under the care of the First Surgeon during the year 1937:—

Congenital megacolon cured by peri-arterial sympathectomy. A boy, aged 12, was admitted on 25th November, 1937, with threatening intestinal obstruction, but the pain, distension, etc., were relieved by enema. The sigmoid colon could be felt occupying the whole of the hypogastric and right iliac regions, was tender and contracting with colicky pains. Barium enema confirmed the distension of the whole colon. Laparotomy done on 20th December, 1937, revealed the sigmoid colon to be greatly enlarged, stretching right across to the right side, its walls thickened, mesocolon hypertrophied. Recto-sigmoid junction appeared to

be markedly thickened and irregular. On a diagnosis of Hirschsprung's disease, peri-arterial sympathectomy was done for a distance of 2 inches along the course of the inferior mesenteric artery to the point where it rose from aorta. Sigmoid anchored to left iliac fossa.

Uneventful post-operative course. Bowels moved regularly twice daily from the third day after the operation. For over a month the boy was under observation and during this period, there was no need to give enema or aperients for moving the bowels, whereas before admission the boy used to have one motion in five or six days. Clinical evidence of improvement was confirmed by barium enema and sigmoid.

Transplantation of both ureters. K., aged 20, was admitted on 18th June, 1937, for traumatic rupture of urethra (intra-pelvic) and fractured pelvis for which supra-pubic drainage had to be instituted. This ultimately resulted in an intractable stricture of the urethra, with persistent supra-pubic urinary fistula. After several unsuccessful attempts to restore the patency of the urethra, it was decided to transplant the ureters to relieve the patient of the discomfort of a supra-pubic fistula. The right ureter was transplanted into the sigmoid colon on 22nd October, 1937; and the left one on 22nd November, 1937. On both occasions the patient had an uneventful post-operative course. Renal function remained satisfactory. Patient was seen three months later in quite good health. Further follow-up has not been possible as the patient did not turn up as advised.

Mr. M. G. Kini was in charge of the second surgeon's wards. To find out the incidence of cancer an attempt was made to record all cases that sought advice, both out-patient and in-patient, in a separate register. The result of this tabulation has been published in a paper entitled 'The Problem of Cancer' in the *Indian Medical Gazette* (Volume LXXII, November 1937). The tabular statement collected from cases from 1931 to 1934 shows the regional incidence of cancer. There were 52 cases of the cancer of palate, 52 cases of cancer of penis, 50 cases of cancer of tongue, and 46 cases of cancer of breast in a total of 335 cases. Cancer of the large bowel also showed a large incidence. Eighteen cases out of 335 were cancer of the large bowel. It is interesting to note that all the cases of the cancer of the penis were among Hindus, confirming the findings of other workers in the field. All cases of the cancer of the palate gave a history of smoking of cigars with the fire-end inside the mouth, a peculiar habit particularly adopted both by the men and women of the poorer classes in this place. The chronic irritation resulting from the fire-end inside the mouth over a prolonged period caused the cancer of the palate in the same way as the Kangri cancer of the navel in Kashmir. There was a case of cancer of the penis in a child aged two years. Most of the cases of cancer of the breast that were admitted were in an advanced condition. Of the 46 cases of cancer, two were in men and 44 women. There was one case of sarcoma of the breast operated in 1934 and keeping perfectly fit up-to-date.

Four hundred and six cases with gastric or duodenal ulcers were admitted from the year 1932 to 1937 in a total admission of 4,416 cases, of these 261 were operated upon.

There was one case of rhinoscleroma which progressed relentlessly in spite of treatment with radium, arsenic, gold and iodine.

There were two cases of cancer of the middle ear cleft. Both were epitheliomata. Both gave a history of middle ear discharge.

There was one interesting case of *Encephalitis lethargica* admitted into E.N.T. wards as the most prominent and leading symptom was headache and pain in the left ear.

The patient, an European male, 30 years old, after a mild attack of nasopharyngeal catarrh was seized with a severe pain in the left ear and headache. His medical attendant sent him to the Ear, Nose and Throat Department of this hospital suspecting it to be a case of acute otitis with mastoid involvement. There was no past or present history of middle ear discharge.

The tympanic membrane was normal. There was no post auricular swelling or tenderness. X-ray of mastoid and sinuses revealed nothing abnormal. The idea of its being a mastoiditis was therefore ruled out and the patient was kept under observation. His behaviour was soon noticed to be peculiar. There was disorientation and irregular tremors were noticed in his tongue leading ultimately to paralysis. Three days later he developed right sided hemiplegia and conjugate deviation of eyes and died. Lumbar puncture and culture revealed no evidence of meningitis. It is unfortunate that no post-mortem examination could be held.

The pain referred to the ear seems to be a root pain in the course of a general disease, *Encephalitis lethargica*.

ANNUAL REPORT ON THE WORKING OF THE CIVIL HOSPITALS AND DISPENSARIES IN THE PROVINCE OF ASSAM FOR THE YEAR 1939. By LIEUT-COLONEL L. A. P. ANDERSON, M.A., M.D., B.Ch., D.P.H., D.T.M.&H. (CAMB.), I.M.S.

COLONEL PHIPSON held charge of the Medical Department throughout the year under review and I have therefore thought it proper that the general comments on the working of the hospitals and dispensaries with which this annual report invariably concludes should be in his own words. At my request he has been good enough to send me the remarks he would wish to make and these are incorporated below—

In my report for 1938 I drew the attention of Government to two of the directions in which the efficient working of the medical department is seriously handicapped; one, the deplorable lack of nursing facilities in the state and state-aided hospitals of the Province, the other, the lack of post-graduate medical training and the over-burdening of government medical personnel with clerical and other work which encumbers them in the discharge of their professional duties. I regret I am unable to report any progress in either direction, as Government have so far been unable to agree to the establishment of a training school for nurses in connection with the Dibrugarh Civil Hospital, nor to make provision for routine post-graduate training nor for clerical establishments in the larger hospitals.

In this report I take the opportunity of referring to certain other matters which have engaged my attention during the year under review. These concern the pressing need for economy in the use of drugs and other medical supplies necessitated, on the one hand, by diminishing budget grants under this head, and on the other, by the upward trend in the number of patients treated in hospitals and dispensaries, together with the rising prices of many drugs and medical requisites in common use. I have made certain suggestions to civil surgeons with the object of reducing the ever-widening gulf which separates what is really needed and what it is possible to purchase within the limits of the grants available. I know I can count on their help and co-operation, but their position is a difficult one which promises to become still more so if prices rise further and budget grants diminish.

During my inspections of subdivisional and other dispensaries I have encountered one pernicious result of enforced economy which is chiefly met with towards the end of the financial year—the dilution of mixtures containing essential drugs, particularly quinine, to a point at which the mixture ceases to be effective. There is no drug which is of greater importance to Assam than quinine, and the supply of quinine-mixture in a non-effective dose is a form of 'economy' which ought not to be tolerated for a moment. But what is the dispensary doctor to do? In the malaria season he is besieged by large numbers of patients clamouring for treatment, but all too often his stock of quinine is too small to last the year out, and no funds are available to cover supplementary indents, and in the latter part of the year, he must face one of two

alternatives: to refuse treatment (the result of which can be easily imagined) or to supply his malaria patients with reduced and ineffective doses, unless the dispensary is fortunate enough to receive a gratuitous supply of quinine from the public health department, a windfall which occurs but rarely. Statistical evidence of the conditions prevailing is afforded by the fact that expenditure on account of medicines on the 1,584,512 patients attending purely out-patient dispensaries in Assam during the year 1939 was no more than Rs. 90,960, equivalent to 11 pies per head and of course still less in the last few months of the year, when stocks are running low.

If we consider the treatment of malaria alone, the amount of quinine and cinchona available during the year 1939 for the 827,190 malaria patients attending all medical department dispensaries amounted to 3,705 lb., an amount which allowed 34.4 grains only for each patient. The minimum amount of quinine necessary for a full course of treatment is 168 grains, and it is obvious therefore that we are attempting to treat malaria in our dispensaries with a dose of quinine which on the average is little more than one-fifth of the dose required to effect a cure, which is of course what should be aimed at with patients attending medical department dispensaries. The discrepancy between the dose given and the effective dose is still greater in the case of those patients attending purely out-patient dispensaries, since the figure 827,190 includes malaria patients treated as indoor patients who are likely to receive full treatment. The amount of quinine and cinchona available for purely out-patients may therefore be taken to be even less than 34.4 grains per head.

How are these difficulties to be met? The remedies I have suggested to civil surgeons include the practice of the utmost economy in non-essential drugs, to enable larger quantities of essential drugs to be ordered, and the purchase of less expensive equivalents for the more popular and highly-priced foreign drugs. The remedies which I now suggest to Government for the consideration are (i) the allocation of increased grants for quinine; (ii) the maintenance of grants for the purchase of drugs at not less than the pre-war level; and (iii) the appropriation of all income derived from the 'One-anna' system, in all local fund dispensaries where it is in operation, not to revenue, but for the sole purpose of supplementing the funds at the disposal of the medical officer for the purchase of drugs and other medical requisites. In state dispensaries this principle is already in operation, but in my view it should be universal throughout the Province, as a recognized policy, and it would help to meet the difficulties, which are being experienced, in providing adequate medical relief for the sick poor of Assam.

Correspondence

SCORPION STING IN HUMAN BEINGS

Sir.—This note from me at such a late date of about five years after the incident may seem strange and surprising. Yet on account of the possible scientific utility of the facts I venture to put before you my observations of the cases of scorpion sting in human beings.

In the columns of 'Mirror of Hospital Practice' of the Indian Medical Gazette of July 1935 there is mentioned 'A case of scorpion "bite"'. It is the sting of the scorpion that is venomous and painful and not the bite. Likely no one has ever suffered from the 'bite' of the scorpion. To call the 'sting' a 'bite' is misleading and wrong.

Further allow me to add to the usual symptoms of scorpion sting enumerated in the attached note to the report, the following which have not been taken note of or probably not observed by the reporters. Within my experience as a medical man for the last 18 years in this town, I had occasion to treat several hundreds of cases of scorpion sting. I have observed in nearly

50 per cent of the cases where males were stung, a marked painful erection of the penis which does not subside even long after the pain of the sting subsides with treatment. This erection has been observed both among boys and elderly males in addition to the usual symptoms.

Among a few of the females stung, I had observed a similar painful excitement of the nipples; and fulness of the breasts. The patients complained of an appreciable warmth in the genital parts with erection of the clitoris in all probability.

This particular effect of the scorpion venom on the erectile tissue, I think, should be taken note of and investigated. It might prove to be a useful therapeutic agent as a sexual stimulant.

C. B. SUBRAMANYAM, L.M.P.

NELLORE,
6th February, 1941.

Service Notes

APPOINTMENTS AND TRANSFERS

THE VICEROY AND GOVERNOR-GENERAL has been pleased to make the following appointment on His Excellency's personal staff, with effect from the date stated:—*To be Honorary Surgeon*

Colonel P. B. Bharucha, D.S.O., O.B.E., vice Colonel H. Stott, O.B.E., vacated. Dated 30th July, 1940.

Lieutenant-Colonel J. P. Huban, O.B.E., Administrative Medical Officer in Rajputana, will continue to officiate as Additional Deputy Director-General, Indian Medical Service, vice Lieutenant-Colonel R. F. D. MacGregor, C.I.E., M.C., granted an extension of leave.

Lieutenant-Colonel J. S. Galvin, Civil Surgeon, Dharwar, reverted to Military duty, with effect from the forenoon of 12th February, 1941.

Major B. M. Rao, an Officiating Agency Surgeon, on return from leave, resumed charge of his appointment of Medical Officer, Meshed, with effect from the afternoon of the 9th January, 1941.

The services of Major M. R. Sinclair, Civil Surgeon, Agra, have been placed at the disposal of Government of India, Defence Department, with effect from 14th January, 1941.

Major R. L. Raymond, on return from leave, resumed charge as Ophthalmic Surgeon, Rangoon General Hospital, on the forenoon of the 3rd February, 1941.

Major R. I. Reid is appointed as Director of Production, Instruments and Appliances, in the Office of the Director-General, Indian Medical Service, New Delhi, with effect from the forenoon of the 4th February, 1941. He will be on probation until further orders.

The services of the undermentioned Officers of the Indian Medical Service (Civil) are placed temporarily at the disposal of His Excellency the Commander-in-Chief, with effect from the dates stated against their names:—

Major M. K. Afridi, 12th August, 1940.

Major S. S. Bhatnagar, 15th October, 1940.

Captain R. L. Haviland-Minchin, 16th December, 1941.

INDIAN LAND FORCES

(Emergency Commissions)

To be Captains (on probation)

Sarveshwar Nath Kaul. Dated 15th November, 1940, with seniority 15th November, 1932.

Chandu Vishindas Ramchandani. Dated 15th November, 1940, with seniority 24th March, 1936.

To be Lieutenants (on probation)

15th November, 1940

Pollapalli Nanjundasetti Ramachandra Setty.

Natesampillai Rangavadiyelu.

Marayath Govindan Naya.

Dineschandra Ramchandra Vaidya.
 Mohamed Ji Ahmadi.
 Shiam Bihari Lal.
 Nazir Ahmad.
 Nirmal Kumar Roy.
 Mohamed Sarwar Khan.
 Ajit Singh Gharjakhia.
 Saehindra Nath Mukerji.
 Syed Hussain Razvi Shahid.
 Valiaparampi Thomas Kuriyan.
 Santi Pada Dutt.
 Vaderbet Ramachandra Kamath.
 Mirza Baqar Hasan.
 Bhagwan Swarup Suxena.
 Nirmal Chandra Roy.
 Sailendra Chandra Das Gupta.
 Padma Nava Bose.
 Narayan Vishwanath Gharpure.
 Krishnadhhan Banerjee.
 Lakshman Seshadri Nathan.
 Tirupulliyur Thiruvengada Ramalingam.
 Prasanta Kumar Chatterjee.
 Anuhsinh Khenkarji Jadeja.
 Manee Rustomji Vacha.
 Arumbakam Nageswaran Ramanathan.
 Rafique Ahmad Riyaz.
 Rustam Cavashah Dorabji Tarapore.
 Chamal Lal Kashyap.
 Manjeri Venkatarama Sarma.
 Anil Krishna Barat.
 Bibhuti Bhusan Mandal.
 Kamal Krishna Seal.
 Jogendra Mohan Sinha.
 Akbar Hussain Hamid.

16th November, 1940

Ahi Bhusan Roy.
 Jampala Ramakrishnayya.
 Manohar Genesh Pendharker.

18th November, 1940.

Bhaskara Memon Ambady.
 Tarakad Ramakrishna Aiyar Vaidya Nath.

LEAVE

The leave granted in previous notification to Lieutenant-Colonel R. F. D. MacGregor, C.I.E., M.C., Additional Deputy Director-General, Indian Medical Service, is extended by 2 months.

PROMOTION

Captains to be Majors

R. M. Lloyd-Still. Dated 1st April, 1937, with seniority 17th May, 1936.

H. H. Mahmood. Dated 10th February, 1941.

Note.—The promotions of Majors H. T. McWilliams and I. Baksh to their present rank are antedated to 4th August and 8th October, 1938, respectively.

T. E. Palmer, O.B.E. Dated 2nd February, 1941.

3rd February, 1941

H. B. MacEvoy.

J. Guthrie.

Lieutenant (on probation) to be Captain (on probation)

T. J. Powell. Dated 5th December, 1940, with seniority 3rd August, 1940.

INDIAN LAND FORCES (Emergency Commissions)

Lieutenants to be Captains

1st February, 1941

L. Nandkeolyar.

B. L. Kapoor.

RELINQUISHMENT

The undermentioned officer relinquishes his commission on the ground of ill-health:—

INDIAN LAND FORCES (Emergency Commission)

Lieutenant S. C. Das Gupta. Dated 1st February, 1941.

RETIREMENTS

Major-General N. M. Wilson, C.I.E., O.B.E., K.H.S.
 Dated 23rd February, 1941.

The following retirement, with gratuity, is permitted:—

INDIAN LAND FORCES

(Short Service Commission)

Captain Z. H. Khan. Dated 3rd January, 1941.

Notes

BENGER'S FOOD DIRECTIONS IN INDIAN LANGUAGES

MESSRS. BENGER'S FOOD LIMITED announce that the directions leaflet enclosed in each tin is now printed in the following five Indian languages:—

Gujerati, Hindi, Urdu, Bengali and Tamil.

This is a new departure.

The purchasers of Benger's Food will obtain the best results by instructing their cooks to adhere strictly to the simple instructions contained in each tin.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints gratis; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

The preparation of reprints entails rearranging the type, so that there is often a delay of a month or more, after the publication of the *Gazette*, before the reprints are ready. If reprints are not received within two months of publication of the *Gazette*, contributors should write to the Publishers.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

TUBERCULOSIS OF THE FEMALE GENITAL TRACT

By M. N. SARKER, M.B., F.R.C.S., M.C.O.G. (Lond.)
Professor of Clinical Midwifery, Medical College,
Calcutta

B. P. TRIBEDI, M.B. (Cal.), D.B. (Lond.)
Professor of Pathology and Bacteriology, Medical
College, Calcutta, and Bacteriologist to the Government
of Bengal

and

J. M. CHAKRAVERTY, M.Sc., M.B.
Clinical Pathologist to the Gynaecological Services,
Medical College Hospital, Calcutta

TUBERCULOUS infection of the female genitalia might occur either as a primary affection of the local site, or as a part of a general infection, the original lesion being in some other organ. Primary genital tuberculosis is rare, the commonest cause being secondary infection of the genital tract, either through the blood, lymphatics, or the peritoneum. Hence incidence of genital tuberculosis in the female is expected to show relationship with the extent of tuberculosis in the general population of any part of the country. Tuberculosis of the uterus presents features which are very similar to malignant disease and, as such, bring in very important complications in the diagnosis. Hence it seems desirable to have some idea of the prevalence of this type of abnormality in Bengal where tuberculosis is rampant.

In view of the above, we are recording our observations from the study of the material that we have collected during the last 20 years.

TABLE I

Showing tuberculosis of the female genitalia as seen from biopsy materials

Total number of gynaecological specimens during the period of 1920 to 1940	..	3,744
Total number of uterine curettings examined	..	853
Tuberculous lesions found on histological examinations:		
Curettings	..	4
Uterus, body only	..	3
Cervix only	..	5
Tube and ovaries combined	..	12
Combined body, cervix, tube and ovaries	..	1
Bartholin gland	..	1
TOTAL	..	26

A few cases that we have observed recently are described below:—

Case 1.—R. D., aged 35, came into the Eden Hospital, Calcutta Medical College, on 8th September, 1937, with the complaint of pain in lower abdomen for the last two years.

History.—She had two children—last one being born 17 years back. Both the deliveries were healthy. Menstruation stopped one year before her admission.

On examination.—The uterus was found to be anteverted and mobile; there was slight thickening of the

right parametrium. The cervix bled on examination. The external os looked unhealthy, granular and ulcerated. An early carcinoma of the cervix was suspected and panhysterectomy was done. On histological examination tuberculous infection of the cervix and fallopian tubes was found. No evidence of any tuberculous lesion anywhere else could be found on clinical examination. The patient was discharged on 23rd September.

Case 2.—S. M., aged 24, came to the hospital on 25th July, 1940, for repeated miscarriages and continuous discharge.

History.—First menstruation appeared at the age of 13 years; married at fourteen. She was quite healthy until two and a half years before her admission. She had altogether five pregnancies of which the first two were healthy. Two and a half years back she gave birth to a full-term dead child; the delivery was uncomplicated. About six months later she had another miscarriage. Since the birth of the dead child her periods (more properly the lochia) did not disappear fully but a continuous discharge with periods of exacerbation was going on all the time for which she came to the hospital.

A dilatation and diagnostic curetting were done on the 31st July, which on histological examination showed the picture of a tuberculous infection (figure 1). Mantoux's test was found to be positive in 1 in 1,000,000. On 30th August, 1940, another curettage was obtained which showed the same picture on histological examination. On 3rd September, a laparotomy was performed which showed the following:—

The greater omentum was found to be projecting downwards in a fan-shaped manner. It was adherent to the base of the urinary bladder. There was a good deal of adhesion in the region of left ovary and tube. The peritoneal surfaces of both the fallopian tubes and the left ovary were found to be studded with small tubercles. The appendix was retrocaecal. The base of the appendix and the cæcum appeared to be much thickened and were studded with tubercles. The mesenteric glands in the pelvis seemed to be shotty but not enlarged. Other abdominal organs seemed to be normal. The uterus, the tubes and the left ovary were removed, which on examination showed the following:—

Both the fallopian tubes showed numerous miliary tubercles on the surface. On cutting these open it was found that both the tubes have become extensively involved with caseous tuberculous process, the lumen was completely occluded in several areas. At the site of junction of the tubes with the uterus on both sides there were cascading areas which contained cheesy material. The whole of the endometrial surface of the uterus showed a nodular appearance which was friable to the touch. At some areas actual haemorrhages could be found. The cervical portion was also similarly involved with nodular areas and haemorrhages (figure 2). There were also other areas of hemorrhage which could be made out to be due to instrumentation during curetting. On making several incisions, through the body of the uterus it was revealed that tuberculous involvement took place throughout the organ. The left ovary was also similarly involved. There was a blood cyst within the ovary.

Histological examination of the different portions of the body of the uterus, endometrium (figure 3), cervix (figure 4), tubes and ovaries all showed typical tuberculous infection with very conspicuous giant-cell systems.

Case 3.—S., aged 40 years, was admitted into the hospital on 29th November, 1940, with history of fever for three months and white discharge per vaginam for the last eight months. She had amenorrhœa for eight months. There was a history of bleeding about a month before this period of amenorrhœa. She had four children of which three were living. The age of the last child was two and a half years. On examination the uterus was found to be normal in size but anteverted and pushed to the right side. A big tender mass was found to fill up the left side of the uterus and the pouch of Douglas. There was a small urethral

caruncle and cervicitis was detected. Urinary sediment showed a few pus cells and yielded no growth on culture.

Blood examination result:—Leucocytes—9,600 per c.m.m., erythrocytes—2,700,000 per c.m.m., haemoglobin—50 per cent, polymorphonuclears—80 per cent and lymphocytes—20 per cent.

Formaldehyde and Chopra's tests were negative.

Stool examination showed much mucus, pus cells and red blood cells in fair number; culture showed only *B. coli*. The patient went downhill with continued pyrexia and died on 23rd December, 1940. The post-mortem examination showed the following:—

The greater omentum was seen to project downwards into the pelvic area in a fan-shaped manner and was adherent to the pelvic wall. There was bilateral plastic pleurisy. Miliary tubercles were found to be scattered all over the lungs with interlobar adhesions on both the organs. In the pelvic cavity a tubo-ovarian mass was detected on the right side. The tubes and ovaries were separated from the mass which was seen to be on the right side of the uterus occupying its whole length and some part of the posterior surface of the uterus. The uterus was densely adherent with this mass and with the rectum. On opening the mass thick yellow cheesy pus came out which yielded β haemolytic streptococcus on culture.

Both the tubes were found to be thick and hard, and on cutting these open, caseating areas were seen (figure 5). Both the ovaries on section were found to be caseous and haemorrhagic. On opening the uterus, the entire cavity was seen to be filled up with irregular protruding masses with haemorrhages at places. The cervix was similarly affected and at the junction of the cervix and the corpus of the uterus a polypoid mass, $\frac{1}{2}$ inch by $\frac{1}{4}$ inch in size, was seen to protrude (figure 5).

The wall of the uterus was sectioned at several places and it was seen that throughout the organ there were numerous greyish-yellow areas with haemorrhages. The wall of the abscess cavity was irregular and about $\frac{1}{2}$ inch thick.

Microscopical anatomy.—Pieces from the lung tissue, liver and spleen showed typical picture of tuberculous infection. In the uterus, the endometrium was completely lost, and had given place to granulation tissue and necrotic areas within which there were many giant cells (figure 6). The wall of the uterus showed the same picture. The polypoid mass in the cervix was found to be a tuberculous granuloma. The ovaries and the tubes showed the same type of lesion. Several blocks were made from the wall of the abscess cavity in the right parametrium. Typical tuberculous lesion was also found there (figure 1). Besides these, Gram-positive cocci were seen in the tissue spaces and within the capillaries in the wall of the abscess (figure 8).

Case 4.—Miss H. A., a cinema actress, aged 25 years, had been suffering from profuse purulent leucorrhœa for some years. Four years ago she had a right-sided Bartholin abscess. Since then she had occasional attacks of pelvic peritonitis. The x-ray examination of the chest showed a small lesion at the apex of the right lung, and she was put under treatment for pulmonary tuberculosis. She continued to lose a good deal of weight. On 12th January, 1937, she was examined and was found to run a temperature of 100°F. There were pelvic inflammatory masses on both sides of the uterus. Gonococci were demonstrated from the secretions of the cervix and the right Bartholin gland. After a preliminary palliative treatment a supravaginal hysterectomy with bilateral salpingo-oophorectomy was performed. Convalescence was somewhat prolonged but otherwise normal. The tubes contained pus which was sterile on culture. No tubercles were present on the peritoneal surface of the tubes. There was an abscess in one of the ovaries. The uterus was normal in size. There was a fluctuant swelling on the anterior surface on the right side of the uterus. It was found to be an intramural abscess. On section the tubes and the walls of the intramural abscess showed numerous tubercles with typical giant cells. This patient did very well after the operation but complained of artificial

menopausal symptoms. She died of meningitis two years after the operation.

Case 5.—A., aged 43 years, a stout person, complained of menorrhagia for five years. She was married when she was 10 years of age and became a widow when she was 12 years of age. Never conceived. It was found that she had an interstitial fibroid about the size of five months' pregnancy. She was then suffering from glycosuria and hyperglycæmia. After careful dieting the sugar level came to normal and a subtotal hysterectomy was done on 5th September. Early in 1939 she was seen again when she complained of a small hard tumour on the labium majus. This was removed and on section showed tuberculosis of the Bartholin gland. The secreting acini and the duct were normal. There was a peri-acinal and inter-lobular inflammation separating the acini. The inter-acinal tissue was well supplied with blood vessels. Tuberculous giant cells were seen in series of sections. But the patient is alive now and does not show any tuberculous lesion anywhere.

From the cases detailed above and those incorporated in table I, the main complaints can be summarized as follows:—

(a) Pain in the back and lower abdomen	4
(b) Signs of cervical erosion with bleeding	6
(c) Tumour on the lower abdomen	9
(d) Only bleeding and discharge	7

The age groups of the above 26 cases are given below:—

TABLE II
Age distribution

10 to 20	1
20 to 30	17
30 to 40	4
Over 40	1
Not noted	3

Table I shows figures from biopsy material; this has the disadvantage of being incomplete, and naturally might not show the true picture. We have also collected the data from the post mortems on tuberculous females that were done during the last twenty years, i.e., the same period from which the biopsy material was collected.

The result is given below in table III. Tissues from all these cases of autopsies were, of course, examined histologically.

TABLE III

Total number of autopsies in females, 1920 to 1940	430
Total number of autopsies showing T. B. in females	67
Pure pulmonary	21
Pure intestinal	7
Pulmonary and intestinal combined	39
Uterus, ovaries and tubes showing combined T. B. lesions	4
Pure tubal tuberculosis	2
Percentage of T. B. in the genitals in cases of females where deaths occurred due to tuberculosis	8.9
Percentage of T. B. genitals in all female post mortems	1.1

Discussion and comments

From the above tables, I and III, it will be seen that from unselected gynaecological biopsy

PLATE XII

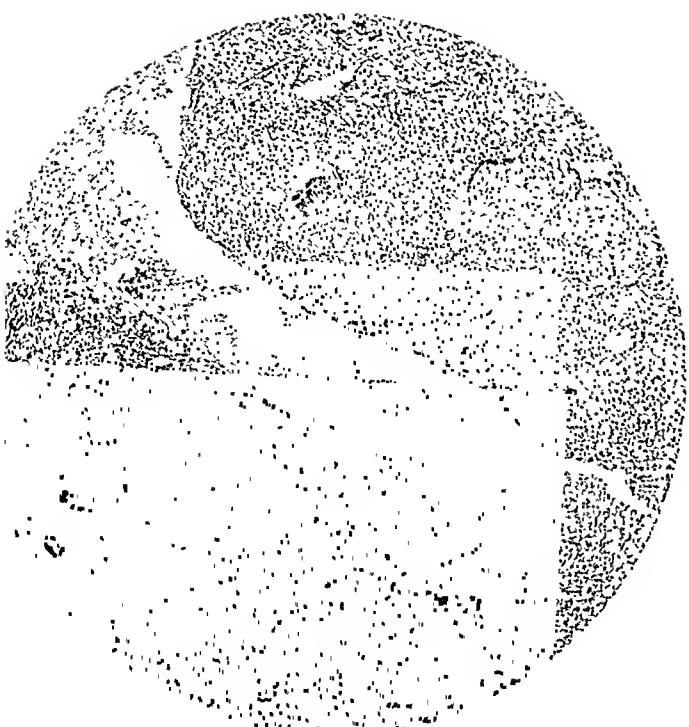

Fig. 1. Case 2.—Photomicrograph of the section from the uterine curettings. Note the caseated area and many giant cells. $\times 150$.

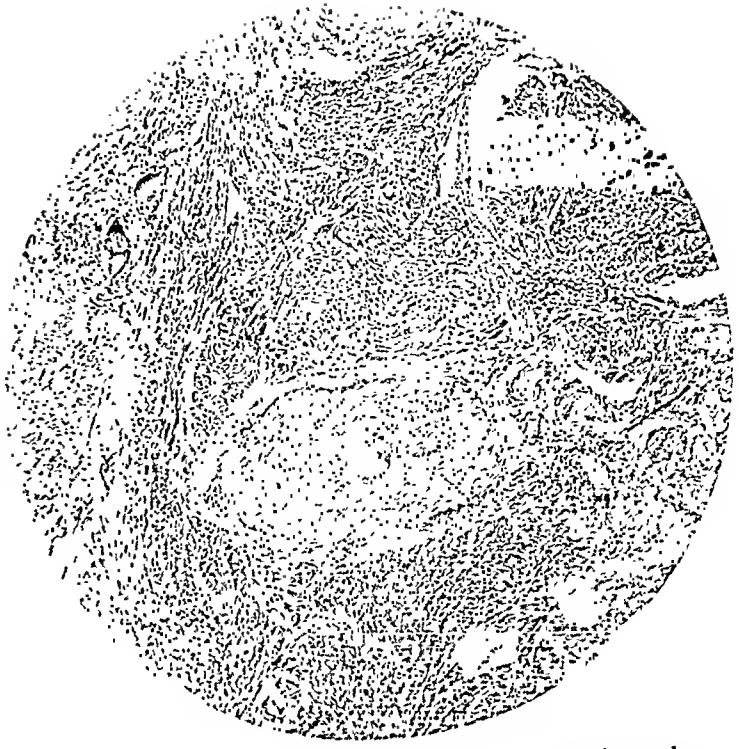

Fig. 4. Case 2. Photomicrograph of the section taken from the cervical portion of the uterus. Note the caseation and a number of giant cells.

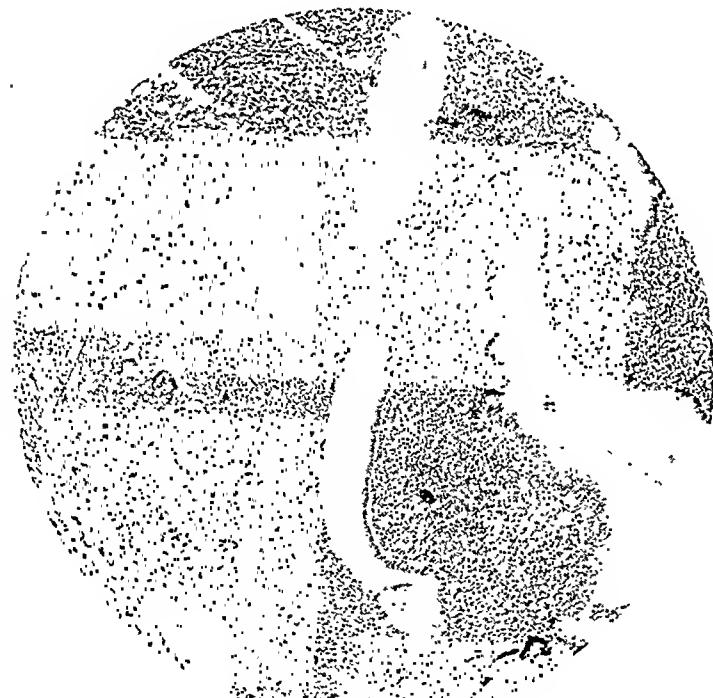

Fig. 3. Case 2.—Photomicrograph of the section from a piece of the endometrium showing the typical tuberculous nature of the lesion. $\times 150$.

Fig. 5. Case 3.—Photograph of the uterus and its adnexa. The thick walled abscess cavity is seen on the left of the uterus. Uterus has been cut open to show the irregular masses which are protruding from the cavity of the uterus. Note the caseating areas in the tubes and the ovaries.

PLATE XIII

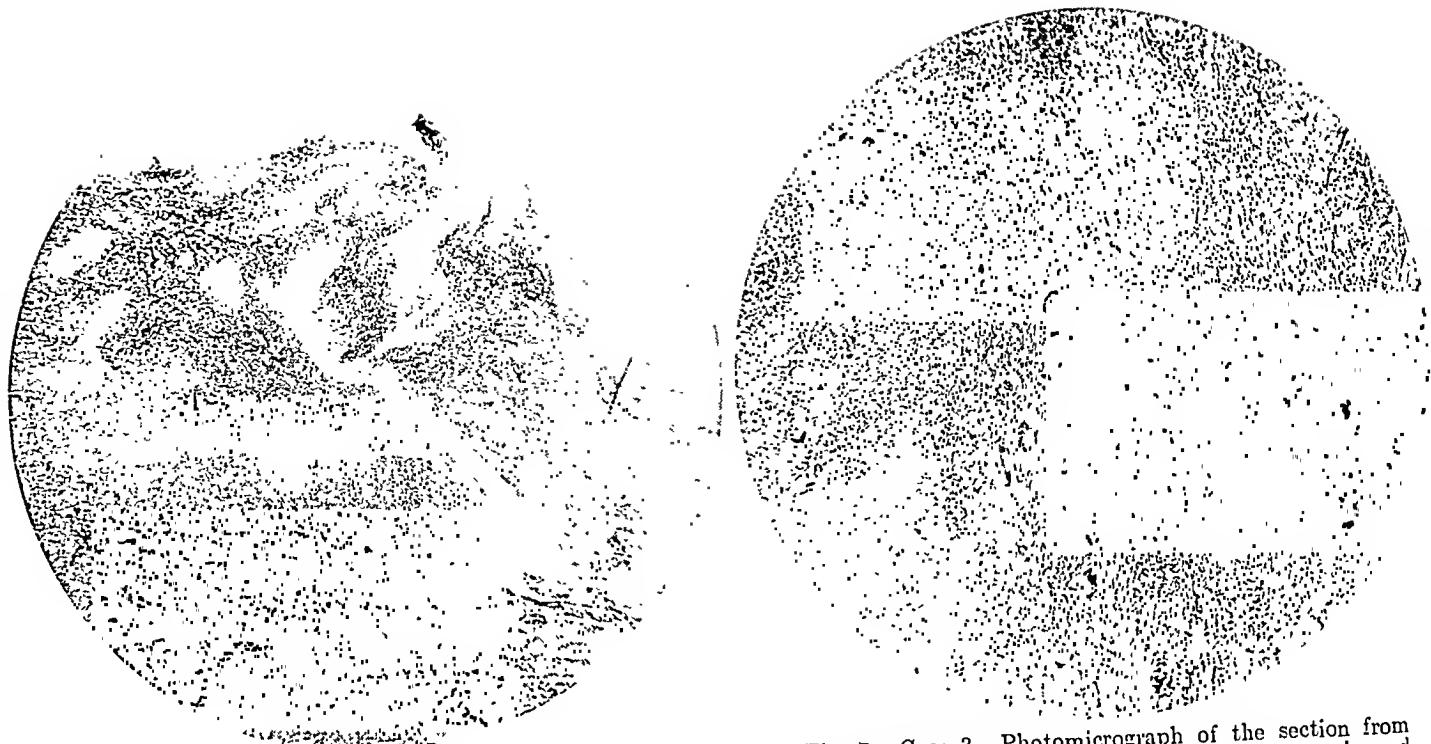

Fig. 6. Case 3.—Low power photomicrograph showing the condition of the uterine endometrium. Necrotic areas and granulation tissue could only be seen. Numerous giant cells are seen which appear as curved black specks in the picture. $\times 30$.

Fig. 7. Case 3. Photomicrograph of the section from the wall of the abscess cavity showing necrosis and many giant cells in the field. $\times 150$.

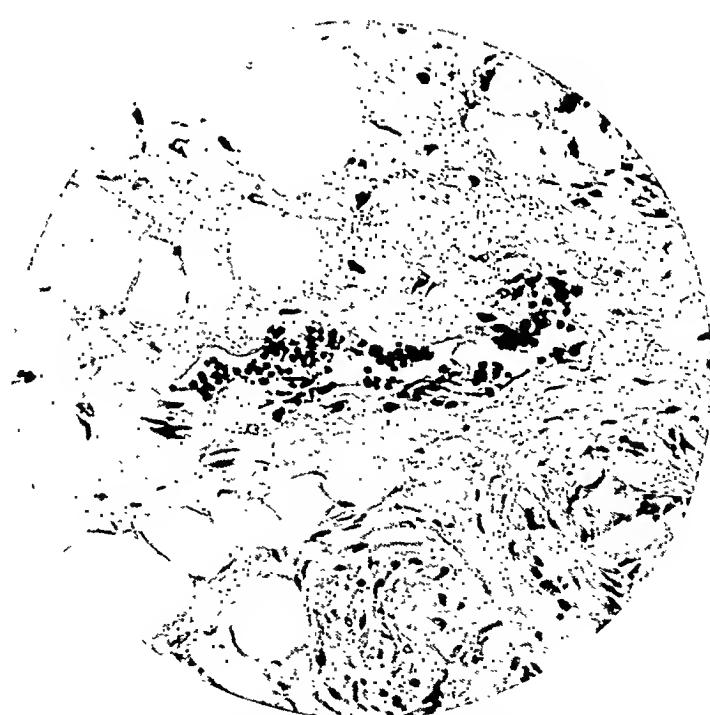

Fig. 8. Case 3.—Photomicrograph of the section from the wall of the abscess cavity showing Gram-positive cocci within a small capillary. $\times 400$.

PLATE XIV

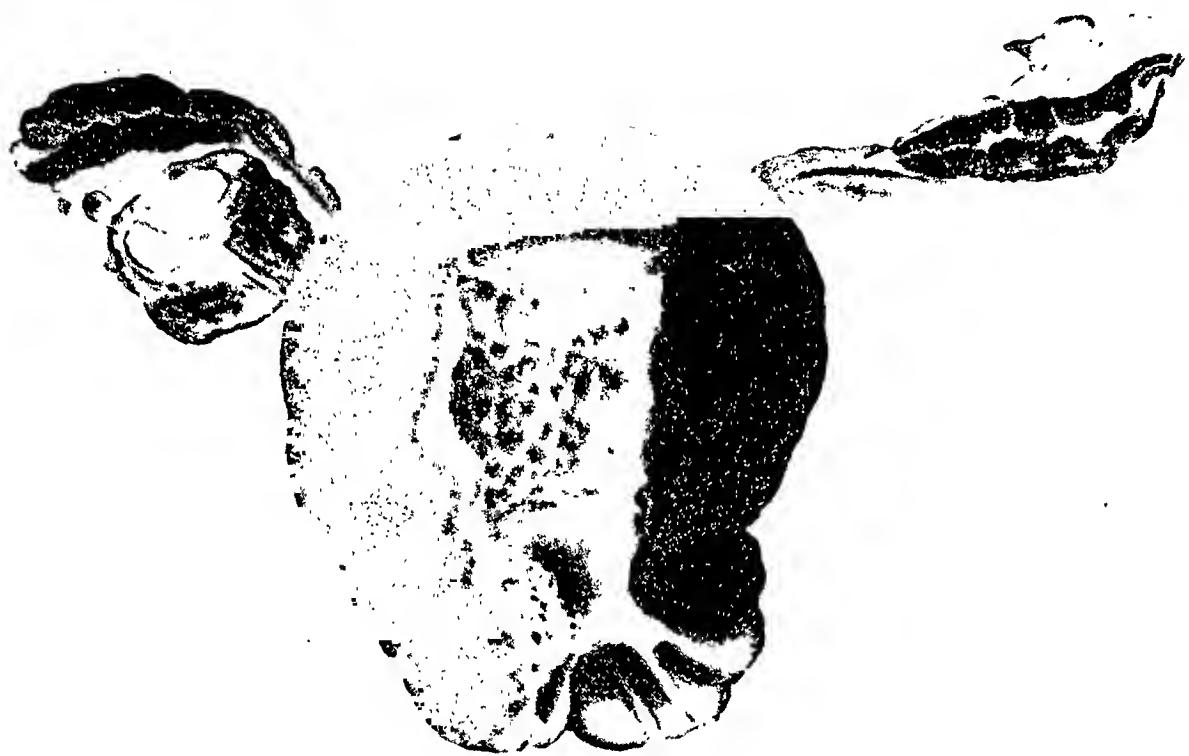

Fig. 2. *Case 2.*—Coloured diagram showing the naked-eye appearance of the uterus, tubes and the left ovary. Caseations and tubercles are seen on the tubes and the ovary. The uterine cavity is filled with nodular masses and haemorrhages. Within the cervix there is a haemorrhagic area on the left which was due to instrumentation.

specimens numbering 3,744 collected within the period of 20 years, 1920 to 1940, tuberculosis accounts for 26 cases, i.e., 0.69 per cent. From unselected post-mortem figures in females only, collected over the same period, tuberculosis of the genital organs occurred in six cases, i.e., 1.1 per cent. Out of the total autopsies of 430 cases in females, in 67 cases death was due to tuberculosis and in these more than 8 per cent of cases showed secondary infection of the genital tract.

Finlaison (1936) quoted figures from different authors which showed that in unselected autopsies in females 1.5 per cent to 3 per cent cases showed tuberculosis lesions in the genital tract, and in cases where death was due to tuberculosis, the figures were from 5 to 12.6 per cent.

The main complaints in our 26 cases were bleeding, tumour and leucorrhœic discharge, which are very similar to the symptomatology of a malignant neoplasm. Without biopsy the diagnosis between tuberculous infection and carcinoma is difficult. The evidence of a tuberculous lesion anywhere else might give a clue. In any case, whether the tuberculous lesion is a primary or a secondary one, the question must remain as a conjecture, in the absence of an autopsy. A hidden primary focus might produce tuberculosis of the genital tract by haematogenous spread.

From table II, it will be seen that most of the cases occurred between the ages of 20 and 40. It is to be noted that this is the age when the incidence of pulmonary tuberculosis is highest. The commonest age for uterine carcinoma is above 40. So it seems reasonable to think that, in any case where there is any suspicion of uterine carcinoma below the age of 40, the question of tuberculosis should be kept in view. In case 2 the spread was evidently through direct continuity, originating from the ileo-colic site. In this case, the body of the uterus showed large caseating areas at the opening of the tubes on both sides, and thus most probably the uterine body substance and the cervical portion got very extensively infiltrated.

In case 3, obviously the tuberculous lesion of the genital tract is a part of the generalized infection, mode of spread being haematogenous, the primary focus being in the lungs. In this case the sites of the tubal openings in the uterus did not show any tuberculous lesion. The damage of the genitals here was more than in case 2, which is natural because of the difference of modes of spread of the infection, the former by direct continuity and the latter by the blood stream. In case 3, streptococcus was isolated from the pus and was demonstrated in the tissue. It seems probable that the streptococcus appeared as a secondary invader, the primary mischief being done by the mycobacterium tuberculosis. Although we did not investigate the pus for the presence of acid-fast bacilli,

CACHEXIA HYPOPHYSIO-PRIVA (SIMMONDS' DISEASE)

(DESCRIBING A CASE CURED UNDER TREATMENT)

By B. B. BHATIA, M.B., M.R.C.P. (Lond.)

Physician to King George's Hospital, Lucknow

In 1914, 1916, and 1919, Morris Simmonds of Hamburg described cases of cachexia of hypophyseal origin, with fatal termination, associated with septic puerperal infarction of the anterior lobe of the pituitary gland. Since then several cases of this disease have been reported in the medical literature and Lichtwitz in 1922 employed the name of Simmonds' disease to them. Up to 1928, Stocks (1930) had collected 34 cases, 4 years later in 1932 Calder had added 36 more.

This disease is more common in the female sex and more cases tend to occur in the second half of life. In most cases the lesion in the pituitary gland is a sclerosing atrophy, but cases

(Continued from previous column)

primary rôle of the mycobacteria is evident. In case 4, the infection of the genitalia must have been blood-borne from the primary pulmonary tuberculosis. She died of meningitis which probably was tuberculous in nature although the exact details were not available. In case 5 the peri-acinal and peri-lobular distribution of the tuberculous lesions would lead one to conclude that the dissemination of the disease was through the blood. Although no other focus of tuberculosis could be found, the primary nature of the involvement of the Bartholin gland is difficult to accept because of the haematogenous nature of the spread.

Summary and conclusions

(1) Three thousand seven hundred and forty-four unselected gynaecological biopsy specimens and 430 unselected autopsies in females, collected between 1920 to 1940, were studied for evidence of tuberculous lesions in the genital tract.

(2) From the biopsy materials the incidence of tuberculosis of the genitalia was found to be 0.69 per cent. From the post-mortem figures the incidence was 8.9 per cent in unselected deaths in females, and where death occurred from tuberculosis the percentage was found to be 1.1.

(3) Five cases of genital tuberculosis in females are described in detail.

(4) Difficulties of diagnosis between uterine carcinoma and tuberculosis are stressed.

Our thanks are due to Lieut.-Colonel J. C. De, I.M.S., Superintendent, Medical College Hospital, Calcutta, for the case records and to the staff of the Department of Pathology, Medical College, Calcutta, for their help.

FINLAISON, F. H. (1936). *J. Obstet. and Gyn. Brit. Empire*, 43, 473.

of septic infarction, inflammation, tuberculous or syphilitic granuloma, tumour and cystic growth have also been reported. In some cases atrophy in other endocrine glands has also been noted and it is difficult, if not impossible, to differentiate such cases from those of pluriglandular deficiency. Some doubt on the pituitary origin of these cases was thrown by Urechia and Elekes (1925). They believed that the primary change in this disease was in the tuber cinereum, and for this reason they labelled their cases *cachexia tuberculosa*. Zondek (1935) has also reported some cases of this disease associated with tumour in the region of the infundibulum and tuber cinereum. In view of the fact that in almost every case of this disease, evidence of deficiency of several endocrine glands is manifested, it seems natural to assume that the lesion must be in some place from where the function of many endocrine glands is controlled. Recent researches have shown that such a place is the anterior lobe of the pituitary gland, which has several hormones that control the activity of other endocrine glands, such as the gonadotropic hormones for the sex gland, thyrotropic hormone for the thyroid, adreno-tropic for the supra-renal, pancreato-tropic for the pancreas, and so forth. It is for this reason that the anterior pituitary is rightly regarded as the 'conductor of the endocrine orchestra' and is in all probability the seat of lesion in this disease. It is possible that in some cases the lesion may have spread to the adjacent portion of the tuber cinereum.

The following case, which was typical of this disease and made recovery under treatment, seems worthy of record :—

Mahadeva, aged 26, farmer from Gonda District, U. P., was admitted under me at the King George's Hospital on the 9th January, 1940, with the following complaints :—

- (1) Progressive emaciation for last six months.
- (2) Great weakness and lethargy.
- (3) Headache.
- (4) Occasional attacks of pain in abdomen, followed by diarrhoea.
- (5) Nocturnal blindness.

In the past, he had suffered from malaria and dysentery about 3 years ago, and since then he had occasional dyspepsia and sexual weakness.

On examination, the patient looked extremely emaciated, anaemic, and toxic with typical senile facies. His weight on admission was 76 lb. The skin was dry, with some patches of pigmentation on the hands, forearms and feet (pellagroid type). There was loss of elasticity in the skin because, when a fold was raised between two fingers, it remained standing. There was loss of hair all over the body, but particularly well marked in the axilla, pubic region and beard area. A few days after his stay in the hospital he developed some oedema on his feet. Thus, briefly, his condition on admission was as follows (figure 1) :—

Weight 76 pounds.

Cardio-vascular system Pulse 60 per minute, regular; blood pressure 80/60; heart nothing abnormal.

Respiratory system .. Nothing abnormal.

Kidneys Urine scanty, average daily 8 ounces, no sugar, albumin or casts.

Alimentary system	..	Hypochlorhydria, mild diarrhoea, with increase in total amount of fat 38 per cent (mostly unsplit).
Nervous system	..	Fundi, nothing abnormal, visual fields normal, deep reflexes absent.
X-ray of skull	..	Sella turcica rather small.
Total red cells	..	2,900,000 per c.mm.
Total leucocytes	..	8,160 per c.mm.
Haemoglobin	..	58 per cent.
General blood picture		Fair number of macrocytes.
Fasting blood sugar	..	60 mgm. per 100 c.c.m.
Blood calcium	..	8 mgm. per 100 c.c.m.
Blood protein	..	Albumin 3.2, globulin 1.5.
Basal metabolism rate		-26 per cent.
Wassermann reaction		Completely negative.

Fig. 1.—Patient on admission.

From the above clinical picture it was clear that he had evidence of deficiency of many endocrine glands, for instance, dry skin, falling of the hair, reduced (-26) B.M.R. slow heart rate and lethargy, indicated deficiency of the thyroid gland; asthenia, pigmentation, low blood pressure, low blood sugar and toxæmia indicated deficiency of the supra-renal (cortical and medullary); low blood calcium showed deficiency of the parathyroid. Disappearance of secondary sex characters (hair over the beard and pubic region) and sexual weakness indicated deficiency of sex glands. He was thus diagnosed as a case of cachexia hypophysio-priva. The alternative diagnosis was that of sprue or chronic pancreatitis, but there was no stomatitis or history of residence near the seaside. Although the stools were fatty, they were not bulky or frothy. Moreover, the increase in total fat was due to neutral fats and not split fats, as occurs in sprue. The possibility of chronic pancreatitis was thought of, but except the character of the stools, there was nothing in favour of this diagnosis. However, for about 2 months he was treated on symptomatic lines, with diet, rest in bed, hydrochloric acid, liver extracts, iron, calcium, marmite and intestinal astringents, but without the least improvement in his general

condition which on the 11th of March was as follows :—

Weight 80 pounds. General appearance same as on admission.
Cardio-vascular system	Pulse 60/70, regular; blood pressure 85/60.
Kidneys ..	Urine 8 to 12 ounces per day.
Nervous system ..	Deep reflexes absent. Fundi clear.
Total red cells ..	3,200,000 per c.mm.
Hæmoglobin ..	76 per cent.
Fasting blood sugar ..	65 mgm. per 100 c.cm.
Blood calcium ..	8.5 mgm. per 100 c.cm.

From this date onwards, he was given a few intravenous injections of glucose with insulin and was then put on antuitrin 'S' one c.cm. (100 rat units) on every alternate day. After about a month of this treatment, he began to show some improvement. The antuitrin 'S' injections were then given twice weekly. Hydrochloric acid by mouth and liver extract were continued for some time, but later on were given up. After 3 months of treatment, he was so much improved that it was difficult to recognize him. The steady improvement was maintained, even when injections of antuitrin 'S' and all other treatment were stopped.

Thus his condition two months after the cessation of antuitrin 'S' treatment was as follows (figure 2):—

Weight 122 pounds.
General appearance ..	Vastly changed from the time of admission, skin was now smooth—pigmentation had disappeared, hair had grown in axilla and pubic region. Senile appearance had gone, there was no lethargy.
Cardio-vascular system	Pulse 80 per minute, regular; blood pressure 120/75.
Kidneys ..	Quantity of urine from few ounces per day had increased to 7 or 8 pints, specific gravity 1005. No sugar (diabetes insipidus).
Alimentary system ..	One or two well formed stools per day. Total amount of fat 24 per cent. Acidity of the stomach within normal limits.
Nervous system ..	All the deep reflexes were now present and fairly brisk.
Total red cells ..	4,900,000 per c.mm.
Hæmoglobin ..	95 per cent.
Basal metabolism rate	+7.
Blood sugar ..	100 mgm. per 100 c.cm.
Blood calcium ..	11 mgm. per 100 c.cm.

However, with this marked improvement all round, one new symptom developed which worried the patient very much, and that was a great increase in the frequency and quantity of his urine. This was however controllable with an injection of 0.5 c.cm. pitressin, given hypodermically once a day.

Discussion

The clinical picture of this case was so similar to the description of cachexia hypophysio-priva given in Zondek's book (1935) that it left no doubt in my mind, as regards the diagnosis, which was further proved by the therapeutic

test. But the actual nature of the lesion in the pituitary gland remained obscure; obviously it was not a tumour, as that would have produced ballooning or deformity of the sella turcica, and there would have been some evidence of pressure on the optic tracts. It was not a syphilitic granuloma, as the Wassermann reaction was completely negative. The possibility of tuberculous granuloma was excluded by the absence of any other tuberculous lesions in the body.

Fig. 2.—Same patient after ten weeks of antuitrin 'S' treatment.

Was it then an early atrophy or subacute inflammation, which improved under treatment, and, if so, in which way was antuitrin 'S' useful? These are some of the questions which are difficult to answer, in the present state of our knowledge. Several recoveries in cases of Simmonds' disease have been previously reported from the use of antuitrin 'S', notably by Hicks and Hone (1935), Dunn (1936), Herman (1936) and Baltzan (1937), but as far as I am aware, none of these reporters have explained how antuitrin 'S' works in these cases.

The appearance of diabetes insipidus in this case during the course of treatment would mean that the lesion, whatever its nature might have been, improved in the anterior part of the pituitary gland, but extended to the posterior part or else that both the parts were simultaneously involved, but the symptoms caused by the deficiency of the posterior lobe were masked by the simultaneous involvement of the anterior lobe. Cases of diabetes insipidus are known to have been relieved of their symptoms by the occurrence of thyroid deficiency (myxoedema). In this case, there was sufficient evidence of thyroid deficiency and that might have been responsible for masking the presence of diabetes insipidus, and, when the thyroid deficiency improved under treatment, diabetes insipidus began to show itself. If it is so, it would mean that antuitrin 'S' had some specific action in stimulating the functional activity of the anterior lobe. That could have been conceived of antuitrin 'S' was

(Continued at foot of next page)

SCARS AND OPACITIES OF THE CORNEA AND THEIR TREATMENT

By G. S. GUHA

Honorary Ophthalmic Surgeon, Government Hospital,
Shillong

IN our country, corneal scars and opacities are common. This is especially so in the crowded streets of big cities. The large majority of the partially blinded and a considerable proportion of the totally blinded are suffering from this ocular affection. The important causes of this group of ocular affections in our country are ophthalmia-nconatorum, neglected conjunctivitis and corneal ulcers, smallpox, irritant drugs, trachoma, and keratomalacia.

These scars and opacities may be due either to the primary affection of the cornea itself (e.g., primary ulcer of the cornea, perforating or penetrating injury, or injury to the cornea by a foreign body or irritant drugs) or to its secondary affection from the spread of an infective or inflammatory process (e.g., neglected acute or chronic conjunctivitis, trachoma, glaucoma, scleritis, episcleritis, cyclitis, and iridocyclitis), a growth from the other parts of the eye (e.g., pterygium), or the result of a specific infective process of the system (e.g.,

(Continued from previous page)

a preparation which represented the various hormones of the anterior lobe, but as it only contains the gonadotropic hormones, like those obtained from the urine of pregnancy, the improvement is hard to explain. I would have liked to give this treatment a trial in cases of marasmus of unknown aetiology occurring in early childhood, if I had a good case in the wards. Except in difference in age, the clinical pictures of the cases of these two diseases very closely resembles each other and it would certainly be worth while to give antuitrin 'S' treatment a trial in marasmus.

syphilis, tuberculosis, leprosy, smallpox, chicken pox, cholera, and rarely influenza, cerebrospinal meningitis, malaria, and kala-azar), deficiency diseases (e.g., keratomalacia), senile and other degenerative conditions (e.g., arcus senilis, axial degeneration of the cornea, band-shaped opacity of the cornea, etc.), neurotrophic disorders (e.g., various forms of herpetic keratitis and lesion of the 5th nerve), or of the spread of certain skin conditions (e.g., rosacea, acne).

Again, such rare conditions as metabolic (e.g., keratitis in gout, sclerosing keratitis in diabetes, central indolent ulcer of the cornea in cachectic conditions in children) and endocrine (e.g., corneal grey spots in myxoedema) disorders, desiccation, exposure, and irritation (e.g., keratitis sicca, keratitis lagophthalmos, in trichiasis, and ectropion of the lids, etc.), pigmentations of the cornea (e.g., metallic pigmentations of the cornea, melanosis of the cornea, and blood staining of the cornea), and congenital conditions (e.g., in congenital leucomata, congenital staphyloma, keratoconus and embryotoxins) may be the cause of corneal scars and opacities.

Before going into the discussion of the treatment of scars and opacities of the cornea, some important facts about the structure and function of the cornea and its pathological variations should be borne in mind.

1. It is an avascular structure and its nourishment depends mainly on dialysis from the periphery. Hence its metabolic process is sluggish and its affection tends to be chronic.

2. Its function depends mainly on its transparency and any slight injury to its tissue may affect this transparency.

3. The extreme sensibility of its epithelium and the imperviousness of its superficial cells to all toxins, except to the gonococcus and diphtheria bacillus, and probably to the pneumococcus are its natural protections.

4. Its epithelium has wonderful powers of regeneration. Therefore any damage of the corneal tissue up to the limit of the epithelium is not of much consequence.

5. Its epithelium is continuous with the epithelium of the conjunctiva; hence it is not difficult to see how the affection of the conjunctiva may also affect the cornea.

6. Its endothelium, like the external continuity of its epithelium with the conjunctiva, has also continuity with the uveal tract; therefore an affection of the uveal tract may affect the cornea secondarily through its endothelium.

7. The sclerotic and the cornea are structurally continuous with each other, both forming the external tunic of the eye; hence any affection of the sclerotic may also spread to the cornea.

8. The Bowman's membrane has little power of resistance and is easily affected. When once destroyed, it never regenerates; therefore some degree of permanent opacity is sure to result after it has been affected.

9. The corneal lamellæ in the substantia propria when destroyed is not reformed, unless the defect is superficial, in which case the loss of tissue is replaced by epithelial growth.

10. Descemet's membrane, unlike Bowman's membrane and the substantia propria, is a highly resistant structure. Therefore it is a great check to external infective processes entering the eye.

11. In superficial injuries of the cornea, the defect is recovered by growth of the epithelium and no opacity of the cornea results.

12. When the injury of the cornea is deeper, regeneration of the epithelium together with the formation of new blood vessels from the periphery result in the growth of connective tissue which gives rise to corneal opacities or scars.

13. If the loss of corneal tissue is extensive and scar tissue formation deficient, the thin cornea is likely to bulge out owing to the presence of the intra-ocular pressure, resulting in an ectasia of the cornea.

14. When the whole thickness of the cornea, except Descemet's membrane is destroyed the latter, being very resistant, may still persist but bulge forward as a result of intra-ocular pressure and thus form a keratocele.

15. In perforating wounds or in perforating ulcer of the cornea, if there is loss of aqueous, the iris may come in contact with the cornea and slowly get attached to it by fibrinous exudate and thus form an anterior synechia and adherent leucoma.

16. In a perforating injury through the centre of the cornea with the escape of aqueous and injury of the lens capsule, the lens capsule may form a synechia with the cornea.

17. If any corneal scar is extensive, incarcerated with the iris and ectasia, anterior staphyloma is produced, which may be partial or total, depending on the extent of the prolapsed iris tissue; when a part of the iris tissue gets entangled in the corneal perforation, a newly formed growth of the iris tissue may form in the scar tissue resulting in the pigment formation of the adherent leucoma.

18. The entangled iris tissue in the perforated area, or the torn capsule of the lens in perforating injuries may keep the opening partially open, so that the aqueous may slowly escape through it, forming a fistula which looks like a black dot on the cornea and which area is stained by fluorescein.

19. If the iris is carried not only into the wound but protrudes through it, the condition is called prolapse of the iris.

20. In advanced cases of injuries to the cornea, penetrating or otherwise, where the lens or especially the vitreous may escape forming a flat opacity of the whole cornea, the condition is called phthisis bulbi anterior. Owing to the sudden lowering of tension in some other cases, there may be choroidal haemorrhage, and the vitreous, retina and choroid may come out with the shrinkage of the whole eyeball, a con-

dition called the phthisis bulbi. Phthisis bulbi may also form as a result of cyclitis.

Left to themselves, scars or opacities of the cornea tend to clear up, especially in younger individuals and when the lesion is superficial, as already explained. Hence age is a great factor in regard to prognosis of vision after corneal affections. Besides having a tendency to clear up, such scars may give rise to pigmentary or other degenerative changes. In extensive scar formation, glaucoma may result with associated degenerative changes in the ciliary body, choroid, retina, and vitreous.

Treatment

1. Prophylactic or preventive

(a) Mechanical protection of the eye by goggles against accidental injuries of the cornea.

(b) Vaccination against smallpox.

(c) Introduction of vitamins in diet to prevent keratomalacia.

(d) Prophylactic or preventive treatment for non-perforating wounds or ulcers against perforation where the prognosis in regard to vision may be grave.

2. Medicinal

Medicinal treatment may be resorted to in more-or-less recent and superficial opacities of the cornea and where there is not much involvement of the neighbouring structures.

Drugs used for the absorption of the corneal scars are mostly those which improve the local circulation. Such drugs are hydrargyri oxidum flavum, dionin, calomel, noviform, jequirity, quinine bisulphate, benzyl-cinnamic-ester, etc., instillation of oily drops, e.g., paroleine may be useful in keratitis sicca.

In addition to the local use of drugs non-specific protein therapy in the shape of milk injections may give good results.

Besides, specific therapy in syphilitic and leprotic cases, as well as tuberculin in tuberculous cases when not too late, may surprisingly clear up corneal opacities. Also local and internal administration of vitamin A is useful in cases of keratomalacia and superficial punctate keratitis.

3. Physical

Physical methods of treatment are used with the idea of producing locally more lymph and peripherally more blood circulation; these are finger massage, electric vibro massage, ultra-violet ray, etc.

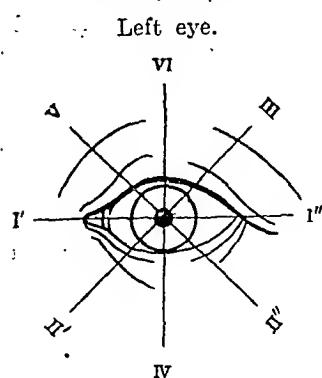

The results of such methods of treatment are very seldom satisfactory.

4. Operative treatment

Satisfactory results are mostly found by operative treatment.

(A) *Optical iridectomy*. In central and deep scars, where there is sufficient clear cornea left at the periphery, optical iridectomy should be done.

The sites of election of this operation should be as shown in the following diagram :—

I' = the best.

VI = the worst (because the coloboma is covered by the lid and is useless for vision).

Optical iridectomy should be as narrow as possible, so that the dazzling effect of light is avoided and stenopic vision obtained. It should not extend to the ciliary border.

(B) *Tattooing of the cornea.* The reasons for tattooing of the cornea are two, *viz.*, (i) optie, and (ii) cosmetic.

(i) A nebula may make vision more

troublesome than a thicker opacity, *e.g.*, macula or leucoma, owing to its dispersive action on light. By tattooing, this dispersive action is stopped and vision becomes more distinct. The optical effect is seldom obtained by tattooing alone especially if the tattooed area covers a large part of the pupillary aperture, unless later on an optical iridectomy is performed.

(ii) The cosmetic effect is obtained by tattooing the thick opacities. If the thick opacity covers the greater part or the whole of the cornea, the middle portion should be tattooed; the central area being thus made darker than the periphery; the pupil is simulated.

There are two methods of tattooing, *viz.*, (i) chemical, where the opaque cornea is dyed by chemicals, and (ii) the introduction of colouring agents directly into the corneal tissue.

(i) Of the chemicals, various solutions have been tried, *e.g.*, gold chloride, platinum chloride, silver salts, iron sulphate and tannin. Of these, platinum is more suitable in our country because of its forming a dense black plaque with a metallic lustre.

The epithelium of the cornea is first scraped off. The chemical solution is allowed to impregnate the subjacent tissue over which the epithelium again grows.

(ii) In the method of introduction of a colouring pigment directly into the corneal tissue, lamp black, candle soot, ink or gold dust have been tried.

Chemical agents give much better results.

Corneal opacities may also be cleverly covered by coloured contact glass, the glass being coloured on the area covering the opacities.

(C) *Keratoplasty or corneal grafting.* This is the ideal operation for corneal scars, but, as it is an extremely difficult operation which should be done by experts only, we shall not give much space to its discussion.

By grafting a clear cornea into the area from where the scar has been removed, the whole cornea looks practically free from any opacity,

and, if the result of the operation is successful there is consequently a considerable improvement of vision.

Three methods of performing the operation have been described, total keratoplasty, superficial lamellar keratoplasty, and penetrating circumscripted keratoplasty; of these the last-named operation gives the best result. In it a small disc of the opaque cornea is removed with a trephine. A graft of the same size is similarly removed from the clear cornea of the eye of a recently dead person or of a recently enucleated eye in which the cornea remains clear. The graft is kept in place by a bridged double suture which extends over it from the conjunctival limbus on either side.

In total keratoplasty, where the whole cornea is transplanted, the after-results are very unsatisfactory. Such a graft gradually becomes opaque and the iris gets adhered to it and either secondary glaucoma results or the eye is lost due to the formation of phthisis bulbi. This operation has been given up now.

In superficial lamellar keratoplasty, a circumscribed superficial lamella of an opaque cornea is removed and a lamella of transparent cornea is grafted on it. The remote results in most cases are unsatisfactory.

In Europe, both on the Continent and in England, very good results have been obtained by keratoplasty. In our country too, similar results of this operation have been obtained by some eye surgeons (Kirwan, 1935).

Operative treatment of corneal scars with complications

(a) In complete perforation of the cornea.

(i) With prolapse of the iris tissue :—Free excision of the prolapsed tissue should be done so that the formation of a staphyloma later on may be prevented and if the wound gapes it should be closed with a conjunctival flap or a corneal suturing and pressure bandaging done.

(ii) If a fistula forms without any prolapse of iris tissue, repeated paracentesis should be done to counteract the intra-ocular tension and thereby help healing and then the wound should be closed with a conjunctival flap. If this fails, cauterization or scraping of the edges of the fistula with a sharp knife, and then suturing the cornea or covering it by means of a conjunctival flap should be tried.

(b) In cases where a staphyloma develops.

(i) When partial :—The adherent iris should be cut with a knife through the anterior chamber or iridectomy may be done on either side of the incarcerated portion of the iris.

If the partial staphyloma be small, it should be split up with a knife and then excised with forceps and then the divided portions sutured or covered by means of a conjunctival flap.

(ii) When total and extensive, enucleation of the eyeball should be done.

NON-SPECIFIC ULCERS OF THE ALIMENTARY TRACT*

By K. MANOHAR, M.D. (Bom.)

(Pathology Department, Seth G. S. Medical College, Bombay)

In the course of a large number of autopsies, a variety of ulcers are seen in the alimentary tract that do not have the characteristic gross appearance of any known specific ulcer. Bacteriological examinations for the determination of causal organisms fail to indicate an infection by any of the usual agents. Chemical examination does not show the presence of any poison, and histological examination of the ulcerated or inflamed areas fails to show any characteristic cell picture.

There is another group of autopsies, in which the clinical history is very strongly suggestive of a specific lesion, but the autopsy findings are very variable and quite unlike the changes usually noted with the specific infections. This group is of great clinical importance from the point of view of the treatment of such cases.

The third group, which will not be considered in detail in this paper, is the group of non-specific ulcers caused by obvious pathological processes like embolism, chronic obstruction, or a neighbouring acute inflammation like appendicitis or salpingo-oophoritis. Non-specific ulcers may also occur as a result of chronic congestion and oedema of the intestine, either in atrophic cirrhosis of the liver or congestive cardiac failure. Although these last are of very little significance from the point of view of pathologists, the symptoms of diarrhoea and blood and mucus in the stool sometimes continue for several weeks and in a few cases dominate the clinical picture at the time of admission to the hospital. In cases of congestive failure with obvious auscultatory changes in the cardiac area, the secondary nature of these symptoms is easily recognized, but in cases where there are no valvular changes, and particularly in cases of cirrhosis of the liver, the diarrhoea and

blood and mucus have led the physician to suspect primary dysentery leading to nutritional oedema.

Non-specific ulcers of the alimentary canal, when considered in their strict pathological definition, thus form a very large and rather indeterminate group. Very often it is felt, that the failure to find a specific cause is more the result of the technical difficulties of investigation, than of a real non-specificity of the causal agent. Most of the workers in the autopsy room are familiar with the difficulties regarding the delay between the death and the autopsy, the difficulty of preventing contamination, the difficulty of a follow up by animal experiments, and the vagaries of serological diagnostic tests.

While the pathologist with his more rigid criteria oscillates between the two extremes of either accepting too many lesions as non-specific, because the specific cause could not be determined, or deliberately including all lesions in one or the other specific group with which the lesions had some similarity, the clinician definitely accepts the group of non-specific enterocolitis as a clinical entity with certain characteristic symptoms, signs, radiological findings and lines of treatment. *Crohn et al.* (1932) were the first to establish this disease entity.

The attention of the writer was first drawn to this group by the description of signs, symptoms, and the morbid changes in the colon, in a group of cases described as chronic non-specific non-ulcerative colitis, in a short article in the Leibig Anniversary volume. The cases are of a type often met with here, both in clinical practice and in the autopsy room. The patients are middle aged; they have a chronic diarrhoea, with occasional periods of passage of blood and mucus; there is a moderate anaemia, oedema round the ankles, and a hint of ascites. Repeated stool examinations fail to show any specific agents. In a few cases on which autopsies are performed, the major change is in the rectum and the ileum. The colon is very slightly if at all affected. The rectum often forms a thickened rigid tube with irregular lumen and small fistulae running into the neighbouring connective tissue, only for a very short distance. The fistulae do not give rise to peritonitis or ischio-rectal cellulitis. The ileum shows a diffuse or patchy thinning of its walls. It is tempting to call such condition a variety of sprue, or bacillary dysentery. But most of the cases have had several lines of treatment for sprue and dysentery without any success. In the article mentioned above, a vaccine treatment had been described. The vaccine treatment will be referred to, in considering the bacteriology of this condition.

A number of articles have appeared recently in the surgical journals describing acute segmental inflammations of portions of alimentary canal, describing these as acute regional jejunitis, ileitis, or colitis. At the same time a series of similar cases were encountered in the autopsy

room. These were studied in detail and form the chief material for this paper.

In going over the autopsy records of the previous years, a number of suggestive case reports were met with, but the descriptions of the condition of the small intestine and colon were not sufficiently clear as to the exact position and distribution of the lesions, and in many cases a diagnosis of chronic bacillary dysentery was put down. In cases with chronic symptoms, both the symptoms and the autopsy findings were exactly like the ones described above. A number of cases with fistulae and fibrosis of the rectum have also been recorded. But the diagnosis is not clearly set down. Gummatous inflammation of the rectum is considered to be the most probable condition. There is one museum specimen in which the diagnosis is left open.

As the acute condition was not recognized as a separate entity, there is no mention, and no detailed description of any lesions in the small intestine which can be construed to be regional enteritis.

Since 1937, the writer has been able to collect forty-four cases of non-specific inflammations of the alimentary canal. The distribution of the lesions was :—

	Acute	Chronic	Total
Cœsophagus ..	8	5	13
Jejunum ..	3	0	3
Jejunum and ileum	4	? 1	5
Ileum ..	4	? 2	6
Mesenteric glands	4		4
Colon ..	6 plus ? 2	? 2	10
Rectum ..	3	7	10

Of the lesions included in this group, the inflammation of the cœsophagus is not strictly speaking a part of the regional enteritis as a clinical group, but they can be included in the group of non-specific inflammations of the alimentary tract.

In the case of the colon and rectum, the writer does not feel satisfied that the number is really representative. This doubt is felt for two reasons. Two of the ulcers were associated with septic endometritis and one with ulcerative endocarditis. On the other hand, a large number of ulcers of the colon appeared to have the mixed characters of amœbic and bacillary dysentery, but no amœbæ could be found in the scrapings or sections and no bacilli of the lactose non-fermenting type could be obtained in cultures. These cases should have been included in the group. Still, because of the similarity with standard lesions, such ulcers have been definitely excluded from the group of non-specific ulcers. For this reason the group of regional colitis is not satisfactorily represented in this series.

The cases of chronic ileitis and jejunitis are also more interesting from the clinical viewpoint than as well-defined pathological entities.

Ulcers of cœsophagus

Acute non-specific ulcers of the cœsophagus were found mainly in the neighbourhood of the

tracheal bifurcation. In two cases they were multiple, in the rest single. The ulcers were longitudinal in one case; in the rest, they were transverse. In all cases they had raised edges infiltrated with blood. The bases were free from slough. Histologically, a moderate amount of leucocytic infiltration was considered to be a necessary condition for considering the ulcers as inflammatory. Lyall (1937), who had studied a series of such ulcers, considered that an aberrant gastric mucosa was found in a majority of these ulcers. In the present series aberrant gastric mucosa was found in only one ulcer. Lyall also found associated peptic ulcers in half his cases. In the present series there was no associated peptic ulcer. All these ulcers were found incidentally. It is not possible to say whether there were any clinical symptoms.

Chronic inflammations of the cœsophagus were chiefly found in cases of anaemia. Four were non-ulcerative in type, one was a chronic ulcer. Of these chronic conditions, four were found in females and one in a male. Definite symptoms of dysphagia were found in one; in two there was pain and vomiting and rapid wasting; in the other two, no clinical manifestations were noticed. In the case of chronic dysphagia, the lower half of the cœsophagus was dilated in a fusiform shape, the walls and the mucous membrane were thickened, silvery grey in colour and thrown into irregular folds. The cardiac sphincter did not seem to be thickened, or ulcerated. The stomach was a little smaller. There was no ulceration or growth in the stomach. On section, the cœsophagus showed a well-marked increase in the submucous connective tissue. The connective tissue was hyaline and showed small collections of mononuclear cells. There was no hyperplasia of the epithelium. The condition could not, therefore, be considered as precancerous.

The other three cases showed a thickened stiff cœsophagus which was narrowed and tortuous rather than dilated. The stomach in all these cases also was free from peptic ulcers or growths.

The chronic ulcer was found to be just above the cardiac end; the edges were so much thickened as to suggest malignancy. The edges, though thickened, were not everted, but shelving towards the base. Sections showed non-specific chronic inflammatory granulation tissue. There were syphilitic manifestations in other organs.

Acute jejunitis and ileitis

The chief characteristic of these lesions is a segmental distribution and simultaneous involvement of all coats in the segment affected. On opening the peritoneum, portions of congested intestine are seen to alternate with portions of normal-looking intestine. Sometimes only one small length may show congestion. Seen at the

earlier stage, the appearance suggests a post-mortem artefact, but the presence of haemorrhages on the serous coat, and usually also red, swollen mesenteric glands, suggest an enteric infection. Seen at a late stage—it seems to be a late stage—the massive congestion suggests infarction due to mesenteric thrombosis.

On opening the intestine, there is a well-marked haemorrhagic infiltration, which may be in patches or diffuse, and the mucous membrane is necrotic in patches, which are raised up into everted, greenish folds, or round areas. Removal of mucous membrane and formation of undermined ulcers was considered to be against the condition being a non-specific inflammation.

The Peyer's patches were occasionally the seat of haemorrhage, but did not show the primary swelling and ulceration, nor the pattern of dilated vessels converging towards them, seen so well in enteric infections.

The chronic lesions were not so distinctive. In four cases they consisted of punched out circular or transverse ulcers more in the jejunum than in the ileum. The ulcers did not show any tubercles at the edges, or on the serous coats. The white radiating lines in the scrous coat, so characteristic of tuberculous ulcers were not present. Histological examination failed to show any tuberculomata. Strictures and hypertrophic thickening are described by several authors under a variety of names, but in this series no well-marked strictures or thickening were noticed.

The other chronic type of lesion was found in comparatively young persons, between the ages of 20 to 30 and in this group also females predominated over the males, 5 to 2; in these, symptoms of diarrhoea, wasting and anaemia were present in four. In two, operations were done for acute abdomen, although there was a history of pain in the abdomen for more than a month.

In these cases, portions of ileum showed a uniform thinning of all coats. The mucosa was covered with an excess of mucus over the thinner areas and while wiping away the mucus, fragments of mucosa were also dislodged. There was no congestion, but in the drainage area of the part one or two sentinel mesenteric glands were found, which were red with yellowish spots, but without any definite pus. Microscopic examination showed lymphadenitis with focal cloudy degeneration.

Although mesenteric glands have been mentioned separately in the table, they were not found as an isolated lesion, but had accompanied either acute or chronic enteritis.

Regional colitis

As explained previously, the number of cases included in this group is more probably too small than too large. In the acute group, only those cases are included in which there was either a simultaneous involvement of the colon and small intestine, or the primary condition of the colon

had given rise to other infective foci in which non-specific organisms were found.

While the lesions in the small intestine were similar to those described by other writers, the lesions in the colon were not of the standard type. The best description of the colon is given by Burke in describing a group of cases, as phlegmon of the colon. 'The involved portion varies from greyish red to purple in colour. The serosa is covered with fibrinous exudate. The bowel feels doughy'.

The lesions in the colon were either circular bands of necrosis with raised everted haemorrhagic margins or round ulcers which differed from those of amoebic dysentery in being raised and everted with greyish coagulated sloughs. The edges were not undermined. The patchy distribution and the round shape, instead of serpiginous outline, were the points by which the ulcers were distinguished from those of bacillary dysentery.

The chronic regional colitis was of the standard type, segments of pelvic colon and rectum being chiefly involved, and thickening and fistula formation being the chief abnormality. Histology was characterized more by absence of any specific appearance than by the presence of a characteristic cell picture.

Symptomatology

The age distribution of regional enteritis is, as might be expected, quite wide. The fact that a large number of cases were less than 40 years of age is more probably due to the fact that the majority of autopsies are done on persons of this age group. At the same time this age distribution must be considered to have some significance, because several authors, such as Clark and Dixon, have found that the majority of surgical cases in the wards are also from this same age group. Sixty-three per cent of Clark's cases were less than 30, and 84 per cent less than 40 years of age.

In the present series the age distribution was as follows :—

0 to 10 2
11 to 20 4
21 to 40 17
41 onwards 8

There is no specially significant sex distribution of these lesions, although in the present series the females were comparatively more commonly affected.

Amongst the thirty-one cases, females were eight and males twenty-three; the symptoms and duration differed according to whether the condition was acute or chronic. In the acute cases, the duration was between 2 to 10 days, and the symptoms were either those of acute abdomen, with or without a lump, of food poisoning, or of enteric fever. In the acute cases laparotomy was done in three instances.

The following symptoms were met with in the chronic or recurrent cases :—

Pain in the abdomen ..	In all cases ..
Diarrhoea ..	" 15 "
Anæmia and wasting ..	" 9 "
Fistulae ..	" 5 "

Radiological investigations were not carried out on any of these, but in the surgical and radiological journals, a tape-like appearance, narrowing and absence of hastrations are described as characteristic findings.

Aetiology

In studying the aetiology, both positive and negative findings must be considered as of significance.

The aetiology of this condition must be considered under two heads : the bacteriological findings and the possible predisposing factors.

In every case of this type, scrapings from the ulcers were examined for amœbæ. Culture of the scrapings was done on Endo's medium. A culture from the heart-blood and from the bile was done on glucose broth. Triple Widal was done with blood from the jugular vein. Only when these cultures and serum reaction failed to show any of the specific organisms giving rise to inflammation of the intestine, were the cases included in this group.

The presence of tuberculous foci elsewhere was also looked for, and, if present, smears from the affected portions of the intestine and neighbouring lymph glands were examined for acid-fast bacilli. Mayo considered that an acid-fast bacillus allied to the bacillus of Johne's disease in cattle is an important causal agent, but, in the present series, if acid-fast bacilli were found, the cases were rejected as those of tuberculosis of the intestine.

The positive findings in this series were *Bacillus coli* from an accompanying meningeal exudate from one case of acute ileitis, and streptococci from two heart-bloods. In one case, there was erysipelas and in another the chronic fistula had given rise to a psoas abscess and pyæmia.

Among the predisposing factors, the presence of worms was given special attention, but it was found that the worms were not more frequent in this group than in the other routine autopsies. In the few cases in which round worms had produced severe disturbances, acute or chronic ileo-colitis was not prominently present.

Anæmia was present in a comparatively large number of cases, but it seemed more often the result than the cause of this condition.

Observations on the bacteriological findings in these cases, are given by a large number of writers. Some are based on the appearance of bacteria in stained section which cannot be given much importance.

NOTES ON COMMON SKIN DISEASES

II. RINGWORM OF THE SCALP

By L. M. GHOSH, M.B. (Cal.), D.T.M. (L'pool)

(From the School of Tropical Medicine, Calcutta)

RINGWORM of the scalp, tinea tonsurans, or tinea capitis, is essentially a disease of children. Children of the school-going age, between 5 and 15 years, are the worst sufferers, but adults may also contract the disease.

The disease is very contagious, the contagion spreading not only by direct contact with the

(Continued from previous column)

Examinations of the contents of resected loops by cultural examinations have given more reliable information. Monroe (1937) gives the following frequency with which various organisms are met with :—*Bacillus coli*, Bargen streptococci, haemolytic coli, *Streptococcus viridans*, *Salmonella*, Gram-positive diplococci, *Bacillus alkaligenes*.

Bargen and his co-workers have investigated rectal swabs of a number of cases. Bargen has given much importance to a special variety of streptococcus. Like the work on streptococci by Rosenow this work has met with very adverse criticism by most writers.

A further detailed study of the coli-like organisms has been done with eosin-methylene-blue medium and a number of organisms have been also studied regarding their action on blood.

Christopher has studied a number of cases of ileo-colitis and is of opinion that amoebiasis plays an important rôle in the earlier stages of the condition. Later, the amoebæ disappear and that is why emetine or other anti-amoebic lines of treatment do not cause any improvement.

Felsen considers that bacillary dysentery may play a similar rôle and this writer examined the sera of such persons for agglutinins. The presence of anti-dysentery phages in the stools of these persons was considered by Felon, as evidence of the bacillary origin of this condition.

The bacteriology of this condition is thus in need of further detailed investigation.

Summary

A description of non-specific inflammations of the alimentary canal based on forty-four cases is given. Thirteen were lesions of the oesophagus, and thirty-one of regional enteritis.

The characteristic pathological appearance of the lesions is described. The chief symptoms were of two types, according to whether the lesions were acute or chronic.

The aetiological factors have been reviewed.

infected children, but also by the use of infected materials, such as hats, towels, hair brushes, combs, etc.

Another source of infection is infected domestic pets, e.g., cats or dogs.

Types

(1) Infection by a microsporon ringworm fungus—microsporosis.

(2) Infection by a trichophyton ringworm fungus—trichophytosis.

(3) Infection by achorion ringworm fungus—favus.

(Favus requires special description and will be dealt with in a separate note.)

In India both microsporosis and trichophytosis occur almost exclusively amongst the European, Anglo-Indian, Jew and Armenian children, and are found mostly in the hill station schools. Once the infection occurs the disease follows its natural course even when the infected children come down to the plains.

Trichophytosis is occasionally seen in the plains, though it is far more common in the hills.

Hair ringworm is not common in Indian children in the plains and *Trichophyton violaceum* is the only species we have so far encountered infecting Indian children.

Signs and symptoms.—Beyond occasional scratching there are hardly any symptoms at the early stage. Usually attention is drawn to it either by the appearance of small bald patches on the scalp or by the inflammation and ulceration due to a secondary infection.

Clinically, the two types of infection are often indistinguishable, without the aid of the microscope. When examined in a good light, one or several pinkish or whitish patches are seen on the scalp. The patches are scaly, the scales being heaped up conically around the hair follicles. The infected hairs become brittle and lustreless and present a dirty-white opaque appearance. The patches are covered with the short stumps of the hairs that have broken off, these project one-eighth to a quarter of an inch from the surface of the scalp; these stumps are bent in all directions owing to a loss of elasticity and are easily pulled out. In some cases of trichophytosis, the hairs break off at the level of the surface of the scalp, and the ends of the stump look like so many black dots at the orifices of the hair follicles. If left untreated these patches become permanently bald owing to the destruction of the hair root.

In advanced cases secondary infection by pyogenic cocci produces inflammation, ulceration, and baldness, due to scars of the healed ulcers.

Examination of the hairs.—If a few infected hairs (which are easily pulled out) are placed on a glass slide and a drop or two of chloroform is put on to them, the hairs turn chalky white. If treated with 40 per cent liquor potassi for about one hour and examined under the microscope ($10 \times 1/6$), the infected hairs from

the bulb to about a quarter of an inch above the surface of the scalp will be seen ensheathed by spores. In microsporosis, the spores are small and form a mosaic, whereas in trichophytosis the spores are arranged in chains like the beads of a necklace.

Differential diagnosis

(1) Alopecia areata.—The patch or patches when first noticed are completely bald the hairs having come out suddenly. In ringworm, the baldness comes slowly. In alopecia the patches are smooth and glossy, whereas in ringworm the surface is scaly and the patches are covered with short broken hairs. In doubtful cases microscopic examination for the ringworm fungus settles the diagnosis.

(2) Seborrhea.—The whole scalp is full of fine branny scales in seborrhea, whereas in ringworm the lesions occur in small patches from which short hairs point in different directions.

In seborrhea the hairs are healthy and do not break, nor come out easily when pulled.

(3) Psoriasis.—This is not common amongst children. The patches are thick and covered with silvery white scales. The hairs in the psoriatic patches are healthy.

Treatment and prophylaxis

For treatment it is not essential to determine the type of infection. A definite diagnosis of ringworm is enough and it must be remembered that all types of hair ringworm are highly contagious. Microsporon infection shows a tendency towards spontaneous cure when the patients attain puberty, and hence more drastic treatments should be avoided in the case of children nearing puberty, and grown-up girls suffering from microsporon infection should not have x-ray treatment unless absolutely necessary.

Prophylaxis.—The infected children should be kept away from others. Their associates, class mates and room mates should also be kept separate from both the infected children and from other healthy children, for four weeks, and during this period frequent and careful inspection should be made for any sign of infection, which should be confirmed by microscopic examination.

The hats, hair brushes, and combs that had been used by the infected children should be burnt, and towels, pillow covers, bed sheets and other linen in use should be frequently sterilized by boiling.

Careful search should be made for infection in pets (cats, dogs, birds, or even ponies).

The children should wear tight-fitting caps made of washable linen, and these caps should be either boiled twice every day (at least 6 caps are required for each individual), or destroyed by burning. The infected children must wear caps all the time and even at night throughout the course of treatment to prevent infected hair being spread throughout the house or school.

Treatment.—The hair should be cut short (*not shaved*), and kept short by frequent cropping throughout the whole course of treatment; the cut hair should be burnt immediately.

The infected hairs should be looked for and pulled out with the help of a pair of epilation forceps; the pull should be gentle and steady, otherwise the hairs will break. Great care, patience and a good deal of time is required every day, but this time is well spent.

The infected hairs look greyish or whitish; they lose their lustre and come out easily when pulled. The hairs thus pulled out should be burnt. At least one hour should be devoted every day for each patient.

The scalp is then washed, first with spirit soap (soft soap, 1 ounce and rectified spirit, 3 ounces) and warm water and then with cold water.

After the shampoo the infected patches in the scalp should be painted with the following paint :—

Thymol	10 gr.
Olei cinnamonis	10 minims
Liq. iodidi mitis	1 oz.

The following ointment is also useful :—

Acidi salicylici	20 gr.
Acidi benzoici	25 gr.
Olei coconut	3 drs.
Lanoline	1 dr.
Hard paraffin up to	1 oz.

Tincture of iodine may also be used.

This treatment should be continued for 6 to 8 weeks. After two months, the suspected hairs should be sent again for examination. Secondary infection with pyogenic cocci superimposed on the ringworm infection is common and in these cases the secondary infection should be treated first and completely cured, before the actual treatment for the ringworm infection is started. The treatment for the secondary infection is symptomatic, for example, fomentation with mild antiseptic lotions such as acriflavin lotion (1-5,000), or carbolic lotion (1-200) every four hours during the day and unguentum hydrargyri ammoniacum dilutum 1-2 per cent applied at night. A lotion containing 2 per cent each of brilliant green and gentian violet made up with 10 per cent alcohol has been found useful.

Depilation by drugs administered internally or by application of local irritants is not advisable, except by those who have had considerable experience with the drugs, as serious results have followed inexpert administration.

For refractory cases and for patients insisting on a rapid cure x-ray treatment may be given. The x-ray treatment must be given by an expert.

When the patients are declared cured of ringworm infection after several microscopic examinations, they should be given new hats, combs, hair brushes, etc.

LABORATORY PROCEDURES, APPARATUS AND IMPROVIZATIONS

By C. L. PASRICHA

MAJOR, I.M.S.

Professor of Bacteriology

and others

(From the Department of Bacteriology and Pathology,
School of Tropical Medicine, Calcutta)

(i) DESICCATION OF CULTURES, SERUM AND OTHER PRODUCTS

By C. L. PASRICHA

and

N. N. DAS

In the recent medical literature, there has been an almost uninterrupted flow of papers describing new methods of desiccation, or introducing some modifications in old methods. It is not the purpose of this paper to describe a new method of desiccation, but to stress certain technical details and amplify certain procedures which it is hoped will be found useful in any method finally selected by a worker.

The method selected for desiccation of small amounts of material in the laboratory was Hartley's (1936) method. It is interesting to note that this method was adopted as the most suitable and practicable for the special purposes of preparing antitoxins and antisera in the dry stable condition for use as standards, and at the time of publication had been in use in Hartley's laboratories for 10 years. This fact alone speaks well for the method. Hartley records data showing the value of desiccation and that dried products remain stable for long periods, and when reconstituted by the addition of water or saline show little or no loss of biological activity. When it is remembered that Hartley had used such substances as antitoxic sera toxin and complement, which can be assayed with very great accuracy, the results obtained stress the practical importance and value of storing biological products in the desiccated state. Unfortunately, this method of storage of biological products has not been applied to any great extent in India, where for obvious reasons (great variations in temperature, difficulties in storage and transport) this method would be of particular value.

In a preliminary survey, several methods of desiccation were tried in the laboratory. Without going into the details of the comparative value of different methods, it can be stated that Hartley's method proved to be the easiest to work with and gave consistently good results. The desiccation in Hartley's method is affected by exposure of the fluid in ampoules to the action of phosphorus pentoxide, *in vacuo* in a desiccator. As, however, adequate supplies of phosphorus pentoxide were not available, gypsum (calcium sulphate), which is much

cheaper and available in large quantities, was used instead of phosphorus pentoxide. Calcium sulphate heated at 200°C. for 6 to 12 hours in a hot-air sterilizer is an efficient drying agent. Approximately 25 grammes of anhydrous gypsum is required for each 1 c.cm. of fluid material to be dried. An additional advantage of calcium sulphate is that it can be reactivated by heat. It is an advantage to connect the evacuated desiccator with a tower of 'activated' calcium sulphate so as to remove the moisture from the air subsequently admitted into the desiccator. As an additional precaution the desiccator is connected to an air-filtering device to remove any gross particles and bacterial contaminants from the air. This filtering device consists of two tall cylinders connected in series, the first cylinder contains a heavy oil covering a long column of glass beads (which serve to break up the air bubbles) through which the air passes and the second cylinder contains an arrangement by which the air goes through a Pasteur-Chamberland candle conveniently set up in a test-tube.

The drying in the desiccator is finally tested by means of a spark-coil detector for vacuum. This consists of primary and secondary coils with an interposed interrupter for direct current. With this apparatus the 220 (or 110) volt current from the main supply is raised to about 10,000 volts high frequency current. The terminal from the resonator coil, when applied on the exit tube of the desiccator proximal to the stop-cock, gives a violet spark in the tube if the desiccation is complete and the vacuum satisfactory. There will be no violet glow if there is any moisture (water vapour) still present in the desiccator. An apparatus for the detection of vacuum is listed in many catalogues of scientific apparatus, but as it was not available locally a search was made for some other apparatus which could be used for this purpose. The violet-ray apparatus available in many hospitals serves well as a vacuum detector. The resonator coil contained in the handle of the apparatus is fitted up with the metal electrode and this when brought to the surface of a tube properly vacuumized gives a violet glow inside the tube. This is an important step in the control of the proper state of desiccation and is valuable in testing the finished sealed ampoules.

Several bacterial cultures, agglutinating sera, bacterial toxins, group sera for blood groups, small-pox vaccine lymph, and cholera vaccine have been dried by this method, and when tested after reconstitution have shown no appreciable loss of activity. The method is comparatively simple and, when controlled by testing the finished products, gives satisfactory results. From the results obtained it appears that in addition to the preservation of certain cultures, toxins, and standard sera, this method will be particularly valuable in storing and distributing small-pox vaccine lymph and bacterial prophylactic vaccines.

Summary

Attention is drawn to the value of desiccation of cultures and biological products in maintenance of activity and in storage and distribution. Hartley's method (using calcium sulphate instead of phosphorus pentoxide) proved to be the most convenient method for laboratory use.

Attention is also drawn to the importance of testing for vacuum both during the process of desiccation and of the finished sealed product. For this, an electrical device is necessary. A violet-ray apparatus, which is available in the majority of hospitals, can be used for this purpose.

(ii) SIMPLIFIED TYPES OF ASBESTOS FILTERS

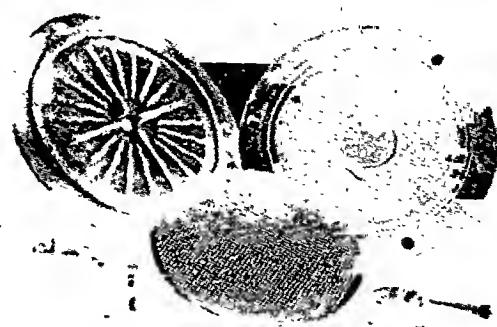

By C. L. PASRICHA

and

K. S. MALIK

Owing to the difficulty in obtaining, under war conditions, filters of the type using asbestos discs, it has been necessary to attempt their manufacture locally, and simplified forms which have been made have been found useful, efficient and cheap. A short description of a large and a smaller form is given below :—

A large type (photographs A and A₁) takes asbestos discs of 5.5 inches in diameter giving a

Photograph A. The larger type shown open. Behind the filter is the asbestos filtering disc and in front is the perforated metal plate.

filtering surface of 5 inches diameter. It consists of two parts held together by three nuts and bolts. There are no screw-in parts requiring washers, and thus there is no danger of leaks developing. This type is found most useful in the laboratory.

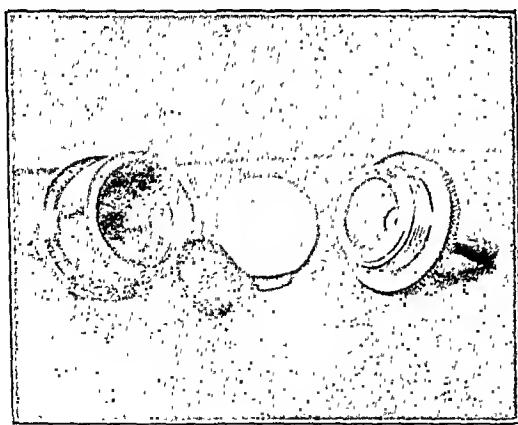

The smaller type (photographs B and B₁) is designed to take filter discs of 1.5 inches in diameter giving a filtering surface of 1 inch diameter. It consists of two parts, one screwing into the other and the disc is held tightly between the two. A circular perforated metal plate (or a circular piece of gauze) is placed

below the asbestos disc to give the necessary support. Discs of the required size can be cut out with a punch of appropriate size. The small-sized filters are particularly useful and economical when small amounts or only samples of filtrates are required.

Photograph A₁. The larger type arranged to filter direct into a series of three screw-capped bottles.

For use both the small and large forms are fitted up with the necessary rubber tubings and placed in suitable metal containers for sterilization. The filtration is carried out under vacuum. Another advantage of the general set up, as shown in the photograph, is that neither

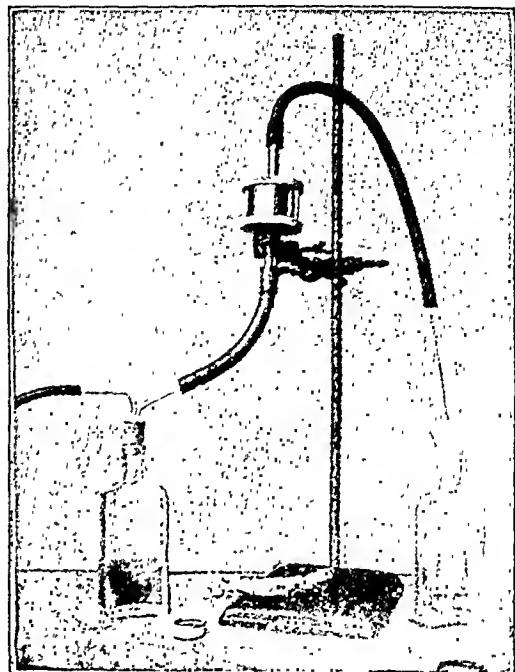

Photograph B. The smaller type consists of two sturdy parts one of which screws into the other. In the centre is the asbestos disc and by its side a circular piece of gauze which fits in a groove below the asbestos disc.

filtration flasks nor large rubber stoppers are necessary. Both these items are expensive.

Both forms are made of gun-metal and are heavily silver-plated or tinned. They were prepared to our design by Messrs. A. C. Dass, 36, Colootola Street, Calcutta, and cost Rs. 10 for the smaller type and Rs. 30 for the larger type.

Summary

Two modified forms of filter using asbestos discs are described. They are simple of construction and have been made locally. They

Photograph B₁. A convenient arrangement of filtering using the smaller type.

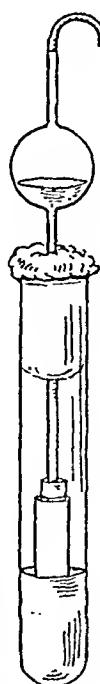

are inexpensive and are simple and efficient in use.

(iii) A SIMPLE SUPPORT FOR MEMBRANES USED FOR FILTRATION

By C. L. PASRICHA

and

A. J. H. DEMONTE, I.M.D.

The accompanying diagram (drawn to one-third scale) illustrates a very simple support for membranes used for filtration. It consists of a Pasteur-Chamberland candle fitted on by means of a short piece of pressure rubber tubing to a glass tube on which a bulb has been blown. As the candle serves merely as a support for the collodion membrane, old discarded candles can be used for this purpose. The tubes with the attached candles are sterilized, and for use the candle is dipped into a standardized solution of nitro-cellulose. The filtration is carried out by suction and the filtrate collected in the bulb on the tube; from this it is removed by means of a capillary pipette.

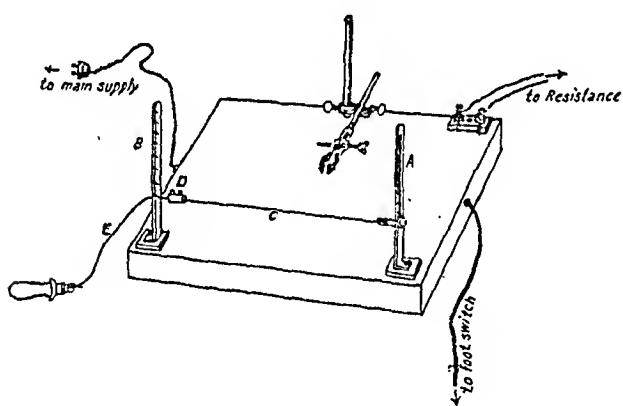

(iv) A SIMPLE METHOD FOR OPENING GLASS AMPOULES AND CUTTING GLASS

By C. L. PASRICHA

Greene and Breazeale (1938) described an ingenious device for opening Keidal tubes. Their method consists of removing the upper portion of the Keidal tube by means of an electrically heated nichrome wire. This method was tried and gave satisfactory results. As the arrangement described and illustrated by these authors was somewhat inconvenient for our requirements certain modifications were introduced. These are :—

1. Instead of the 'on-off' switch on the apparatus board, a press switch controlled by the foot is employed. This allows of better control over the heating of the wire.

2. Instead of mounting the resistance on the board it is more convenient to have the resistance at a distance. A suitable rheostat is used, or a resistance can be prepared by winding nichrome wire on a length of fire-clay pipe suitably mounted on a board. The length of wire necessary to obtain the required resistance is found by trial.

3. Instead of short fixed terminal posts, tall brass pillars (A and B) are used and so arranged that the nichrome wire can be adjusted at any desired height. Pillar (A) contains a longitudinal opening through which the holder for the thin wire passes. This holder can be adjusted at any point by means of a nut and screw. Pillar (B) has a number of obliquely cut slits. The slits are sufficiently wide to allow the wire attached to the handle to be readily inserted. This arrangement allows of the use of the apparatus for cutting the neck of small ampoules or large-sized tubes or even bottles. It is an advantage to have the thin nichrome wire (C) which serves as the hot wire connected with a 'connector' (D) to a thicker wire (E) which is joined to the wooden handle. This gives a firmer control of the heated wire and also prevents sparking and breakage of the thin hot wire, if contact with the pillar is disturbed. Nichrome wire of about 0.3 mm. thickness serves well for the hot wire.

The wiring of the apparatus is simple. One terminal from the main supply is connected with pillar (B), the other terminal passes through the foot press switch and then through the resistance to pillar (A).

To use the apparatus the thin nichrome wire is wound around the neck of the ampoule, or the tube, or bottle at the point where it is desired to cut, and contact made with pillar (B) by passing the wire into one of the slits. Care must be taken that the wire from the two ends of the loop do not make contact with each other. This is easily done by adjusting the level of the wire. The wire is kept taut by traction on the handle. This traction must be maintained during the subsequent heating of the wire as it expands appreciably. The current is turned on by pressing the foot switch. The wire becomes red hot and after about $\frac{1}{2}$ to $\frac{3}{4}$ minute (depending on the quality and thickness of the glass) a minute drop of water is applied to the glass at the level of the wire loop and the glass cracks clean at the level of the loop. Water is not necessary for soft glass tubes. They crack readily with the hot wire. It should be noted that the loop of nichrome wire which goes round the glass does not glow red hot. Ampoules and small-sized tubes can be clamped in the clamp fixed on the board (shown in the diagram).

For opening ampoules of vaccines, sera and other material where it is important to avoid extraneous contamination this apparatus is arranged in a 'hood' and after the necks of the ampoules are thoroughly cleaned (conveniently done by arranging the ampoules necks down, dipping into carbolic acid in short stumpy test-tubes), the necks are cracked with the hot-wire loop. A sterile throat swab moistened in sterile water is used or a drop of sterile water from a pipette can be used.

The device has proved sufficiently useful, efficient and simple of operation to warrant a short note on the modified form. The accompanying drawing gives the general plan of the apparatus which can be made in any laboratory. The cost of the materials used in building up the apparatus is about four rupees (or six shillings).

(v) METAL PETRI-DISH COVERS

By C. L. PASRICHA

and

K. BANERJEE

The breakage of glass petri-dishes during use, sterilization and more particularly during cleaning is a matter of no little importance to many laboratories. It was estimated that with two hundred and fifty pairs of petri-dishes in circulation the life of glass petri-dish is about 4 to 5 months. It is extraordinary how often the glass lids alone are broken and a number of unpaired petri-dishes accumulate. Many of these are used for various purposes in the laboratory and

a number of such dishes are discarded periodically. In order to bring into use this otherwise useless stock of dishes metal petri-dish covers were made. The metal lids were made of such size that would fit the majority of the unpaired dishes. The metal aluminium was selected as dishes of the requisite shape and size are punched out of a sheet of aluminium and do not require any soldering.

Aluminium covers were tried and gave satisfactory results. They have no deleterious effect on the growth of organisms. In spite of the increase in the price of aluminium during the present war conditions, the covers are not expensive and as they are unbreakable their initial cost is negligible. A small stock of metal covers is a very useful addition to the equipment of a media room. A few paired metal dishes will be found of great value. In an emergency when sterilized petri-dishes are not available, the metal dishes can be sterilized by heat over a naked flame and media poured into them as soon as they cool, which they do in a comparatively short time. Such plates are however suitable only for that type of work (e.g., with opaque media) where the characteristics of the surface colonies are studied by reflected light and are of diagnostic value.

(vi) PORCELAIN LIDS FOR PETRI-DISHES

By C. L. PASRICHA

and

K. BANERJEE

Although porcelain covers for petri-dishes are in use in some laboratories abroad, as far as the writers are aware such covers are not available nor used in India. Porcelain covers were made to our design by the Bengal Potteries Ltd., 45, Tangra Road, Calcutta. They are of unglazed porcelain and dull white colour. These covers have proved exceedingly satisfactory. The unglazed porcelain allows of the rapid absorption and evaporation of the water of condensation, leaving the surface of the medium free from excessive moisture. A series of freshly poured plates were inoculated (so as to obtain isolated colonies) with a number of cultures, one set of plates were covered with glass covers and a parallel set with porcelain covers. The resulting growth in the glass-covered petri-dishes were unsatisfactory, as the colonies had coalesced owing to the moisture on the surface of the medium, but, in petri-dishes covered with porcelain covers, the growth was in each case satisfactory and isolated colonies obtained. The porcelain covers stand sterilization well. Once used even the most conservative of workers will find the porcelain-covered petri-dishes distinctly better than the usual glass-covered petri-dishes. They are particularly valuable during the rainy season when owing to the humid atmosphere it is difficult to keep a stock of satisfactorily dry plates. The porcelain covers cost a little less than glass covers.

(vii) COVERSILIP—SUBSTITUTES

By C. L. PASRICHA

and

K. BANERJEE

Since the outbreak of war, the price of coverslips has increased to such an extent that it is a matter of serious concern to many laboratory workers and institutes where a large number of coverslips are used daily. The price of the ordinary quality coverslips before the war and during the first 16 months of the war is given below :—

Before the war Re. 1-7-0 per ounce.

After the outbreak of the war.

28-11-39	Rs. 2-13-0 per ounce
22-12-39	3-0-0 "
28-12-39	3-7-0 "
8-8-40	3-12-0 "
25-9-40	4-4-0 "
7-1-41	5-0-0 "
6-2-41	7-0-0 "

There is every indication that the price of coverslips which now is nearly five times the price before the war will increase in future. It was decided therefore to try other materials that can be used instead of glass for coverslips. The two materials found satisfactory are mica, and cellophane or other transparent cellulose material. Old x-ray or photograph films (after removal of the outer silver-impregnated coating in warm water) are better than cellophane sheets. They do not scratch or mark as readily as cellophane sheets. Coverslips of desired size are cut with scissors or with a photograph trimming machine. Coverslips cut from x-ray or photograph films are satisfactory for microscopic examination of urine, stool, and other material. The slight blue tinge in some of the x-ray films does not cause any distortion of the field, but is actually soothing to the eye, particularly with artificial light. If desired the blue colour can be removed by soaking the coverslips in acidified methylated spirit. There is no loss of definition and the coverslips cut out of cleaned x-ray films are free from any disturbing scratches. Because of their tendency to curl, the cellulose coverslips are not satisfactory for use with the oil-immersion lens or for mounting tissue sections.

Mica coverslips are particularly good and in spite of some wastage due to a certain number of mica sheets being defective (irregular or containing air pockets) the cost of mica covers is extraordinarily low. The material to make 100 coverslips costs a little less than 1 anna (about 1 penny). The present-day price of glass coverslips is Rs. 7 per ounce (approximately 220 coverslips), or about half an anna for each coverslip, whereas the material for a hundred mica slips costs only one anna. The mica slips lie perfectly flat, are free from scratches, and can be made of any desired thickness. Mica coverslips of 0.025 mm. thickness can be made and are easier to handle than the thin glass slips. They can be used for all ordinary microscopic

purposes and because of their low cost no attempt is made to remove them after use.

Summary

As substitutes for glass coverslips, the price of which has increased considerably since the outbreak of war, coverslips cut from old x-ray or photograph films (after removal of the gelatine coating), or from mica sheets give satisfactory results.

(viii) A DOUBLE LOOP FOR BACTERIOPHAGE WORK

By C. L. PASRICHA

A loop of the type shown in the text-figure has been in use for some years and has proved exceedingly useful in putting up cross-tests for the determination of the type of phage, or in testing the susceptibility to bacteriophage of strains of bacteria. In both these tests, loopfuls of bacteriophage are placed on long strips of inoculums of the secondary cultures or of the strains under test. When the ordinary single loop is used this entails the opening of the tube containing the test bacteriophage and charging the loop with it separately for each culture. By the use of the 'double loop' the number of times the loop has to be charged is halved. This saves considerable time and reduces by half the somewhat irksome and tiring process of adding drops in performing a cross-test.

The loop is made of nichrome wire of approximately 0.5 mm. thickness. The two small loops face one another. The sterilized 'double loop' is put into the bacteriophage suspension and lifted out edgeways (not with the flat surface of the loop parallel with the surface level of the fluid). By withdrawing the loops 'edgeways' the two small loops contain equal amounts of bacteriophage and there is no tendency for the fluid in the two loops to run into one another as happens if the loops are withdrawn flat surface upwards. After withdrawal one loop is touched gently on one inoculum and then by turning the handle round the other loop is touched on the second inoculum.

(ix) A SIMPLE EASILY-PREPARED COVER FOR MICROSCOPE AND OTHER APPARATUS

By C. L. PASRICHA

and

K. BANERJEE

A description of a simple easily-prepared dust cover for microscope and other apparatus is given below. Such covers have been in continuous use for more than 3 years and have given entirely satisfactory service. The dust cover consists of five tin-framed 'cellophane' panels soldered together as shown in the text-figure. It is advisable to reinforce the soldered joints by a bent

strip of tin and to paint the tin surfaces. Old x-ray films can be used in making these covers. There are many advantages of a cover of this type over the glass bell-jar dust cover. Some of these advantages are enumerated below :—

1. Dust covers of any desired size can be prepared in the laboratory. All that is required is sheets of transparent cellulose material (or old x-ray films), tin sheets and a soldering apparatus. Their cost is a very small fraction of the price of glass bell-jars.

2. They withstand a great deal of rough treatment and are almost unbreakable.

3. Because of their lightness there is no danger of damage to any screw or other projecting part of a microscope or other apparatus over which such covers are used. When a bell-jar is used, great care must of course be exercised in placing it over the microscope, lest it strike and damage any part of the instrument. No such precaution is necessary with these light covers.

4. By making the covers of graded sizes so that one fits into the other it is possible to prepare a 'nest' of covers, and thus to save considerable space in storage and transport.

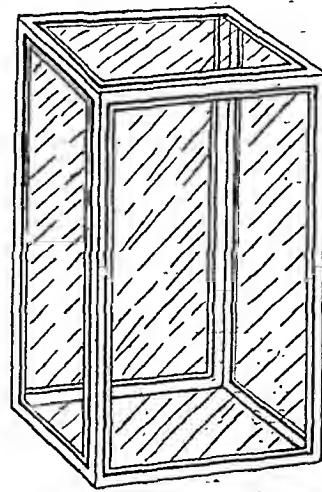

5. If desired pieces of rubber tubing (cut longitudinally) can be fixed on the sides of the mouth of the dust cover.

6. The dust cover can be painted a light yellow or red on the inside to filter the light. Black paper (from the coverings of old x-ray films) pasted on the inside of the cover is satisfactory.

(x) WAR-TIME ECONOMY IN THE LABORATORY

By C. L. PASRICHA

With the reduction of supply of both raw materials and finished products and the need for economy under the present war conditions, it is being increasingly realized that there is wealth in scrap or waste materials that are usually thrown away or disposed of at a very low price. Prices are rising and stocks are diminishing, and it is desirable therefore not only to prevent waste, but to explore every opportunity of salvaging and utilizing what would otherwise be discarded. For example, old x-ray films, photograph or cinema films are as a rule thrown away, or sold at a nominal price. These old films can be put to good use in the laboratory. After removal of the photographic film (easily done by hot water), the cellulose material can be put to a number of uses : (1) for framing photographs, charts, and

diagrams, (2) cut into small squares it can be used as coverslips, (3) dissolved in acetone or alcohol and ether, or amyl acetate, it forms an excellent substitute for collodion, and can also be used for cementing glass. Serviceable cellulose caps for bottles can be made from solution of old x-ray films. As further examples of the utilization of waste material or substitute materials the following are cited :—

1. Cotton-wool plugs, etc., can be salvaged and can often be utilized at least once again.

2. Instead of using brown paper for wrapping laboratory apparatus for sterilization, old newspapers which cost but a fraction of the price of brown paper are satisfactory for this purpose.

3. For filtration of coarse material, as for example before filtration through candle filters or asbestos discs, the material is passed through a column of fine quality sand instead of Kieselguhr.

4. As a substitute for cedar-wood oil for microscopy liquid paraffin is used by many workers. It is not often realized that there are many oils (locally available and at small cost) which can be used. Of these ground-nut oil can be used except where very critical definition is required. Hydnocarpus oil gives better definition than many samples of liquid paraffin.

5. Agar agar—The price of agar has increased considerably since the beginning of the war. Whereas the price was Rs. 3 per pound before the war, it is now Rs. 9-8 a pound for very inferior quality agar. It is possible to salvage a considerable amount of agar from used plates, sterilize it and use it again for ordinary routine purposes. Such agar is satisfactory for the growth of the less fastidious bacteria.

6. Instead of using flasks (which are considerably more expensive now than before the war) bottles of appropriate size can be used. A number of such bottles can often be found amongst the empty bottles that accumulate in a laboratory or in the central stores of a large institution. Bottles of good quality glass are manufactured locally and can be purchased at reasonable prices. The quality of the glass can be easily tested by standard methods (*British Pharmacopœia* : Appendix). Bottles have been introduced for the preparation and storage of media and have proved entirely satisfactory. They stand sterilization well.

7. Instead of wooden packing cases for small specimens sections of bamboo can be used. The bamboo cases are so cut that one side is closed by the natural joint and the other side is closed with a cork or a piece of pith and paper reinforced with wire.

The above are some examples of the many ways in which economy can be effected without loss of efficiency. Such examples can be multiplied many times and will suggest themselves to laboratory workers. These are cited in the hope that they will stimulate workers to develop

(Continued at foot of next column)

THE STERILITY OF SNAKE VENOM SOLUTIONS

By C. L. PASRICHA
MAJOR, I.M.S.

*Professor of Bacteriology and Pathology
and*

Z. ABEDIN

(From the Department of Bacteriology and Pathology,
School of Tropical Medicine, Calcutta)

The haemostatic effect of viperine venom and the analgesic effect produced by cobra venom have made venom therapy a popular form of treatment, particularly in chronic painful conditions. In addition to these specific indications snake venoms are in considerable vogue in some centres and are administered in an increasing number of clinical conditions. The venom preparations are used differently, (a) by direct local application, or (b) by intradermal, subcutaneous, or even intravenous injections.

A severe reaction after a subcutaneous injection of snake venom led to the examination of the venom solution that had been used. This solution contained many viable bacteria. A further 24 samples of venom solutions were examined for sterility. Standard methods of testing were employed, using sufficient fluid medium to ensure that the preservative content of the final dilution shall be less than 0.01 per cent. For the purposes of this calculation the maximum content of the preservative was taken to be 0.5 per cent. Each venom was examined for the presence of aerobic and anaerobic bacteria. The results are summarized below :—

Venom	Number examined	Number passed sterility test	Number not passed sterility test
Cobra ..	11	9	2
Viper ..	14	8	6

The crude venoms when collected are grossly contaminated and the difficulty of obtaining sterile solutions of venoms are well known to all responsible for the preparation of such solutions. Many methods have been advocated for the preparation of sterile solutions. The most satisfactory solutions (as far as the sterility

(Continued at foot of opposite page)

(Continued from previous column)
such alternative methods and to report them. It is the simple and obvious alternatives that are so valuable and are so often missed.

MAINTENANCE OF BACTERIAL CULTURES

By M. K. KRISHNA MENON, M.B., B.S.
*(From the King Institute of Preventive Medicine,
 Guindy, Madras)*

In most laboratories in the North American Continent and in England, the older methods of maintaining bacterial cultures by constant subculturing in suitable media have of recent years been largely superseded by the method of rapid freezing and dehydration *in vacuo*. As early as 1896, Martin suggested the possibility and procedure involved in the preservation of guinea-pig complement in the dried state. Noguchi, in 1907, dried complement and amoebocyte on filter paper. Shackell, in 1909, dried complement in the frozen state and showed that it could be preserved for months. Karsner and Collins, in 1919, applied Shackell's method for the preservation of various sera and, in 1923, Hartley and his associates reported the dehydration of complement by distilling off the H₂O *in vacuo*. In 1931, Craigie dried complement in the frozen state by means of a vacuum desiccator and more recently Elser and his co-worker (1936) showed conclusively that biological materials could be dehydrated from the frozen state. This method was admirably developed by Flosdorf and Mudd (1935) in the University of Pennsylvania and resulted in their dry ice 'lyophile apparatus' by means of which many biological materials could be preserved for several months without any detectable deterioration. The same investigators, in a later communication, in 1938, described a new process where the condensation of water vapour in a low temperature bath (dry-ice methyl cellosolve mixture) is replaced by the use of an inexpensive chemical desiccant (the Cryochem process). The method has been very profitably employed for the preservation of various anti-toxins, guinea-pig complement, human plasma for purposes of transfusion, normal and convalescent human sera, enzymes, viruses, bacteria and miscellaneous proteins.

The procedure and apparatus to be described in this communication are a modification of the 'Cryochem process' described by Flosdorf and Mudd in 1938. This has been successfully employed in the preservation of bacterial cultures though it can be used for preservation of sera, protein solutions and other labile biological materials with equal success.

The apparatus

A diagram of the apparatus is shown. The containers used are a number of 1 c.cm. ampoules

(Continued from previous page)
 tests are concerned) were obtained with solutions that had been filtered through an asbestos filter. These results are recorded to draw attention to the importance of control by sterility tests of injectable substances.

which are attached to pressure tubing. Any number of containers can be attached by using a multiplicity of glass Y-tube connections. The attachment of the containers leads to two glass cylinders containing either fresh or freshly regenerated anhydrous calcium sulphate (known under the trade-name drierite). Drierite is a comparatively low cost chemical with a powerful affinity for water and is capable of producing a low aqueous tension very rapidly. Also it has no vapour pressure of volatile substances and can cause no harmful effects on labile materials such as has been reported with H₂SO₄ or acid phosphoric anhydride. An additional advantage is that used calcium sulphate can be regenerated for further use by heating for about 6 hours in an oven at 150°C. to 250°C. (180°C. is optimal). The glass cylinders containing drierite are connected to a mercury manometer and a Cenco-Hyvac pump.

The operation of the Cryochem apparatus

The apparatus should first be tested for vacuum tightness with the outlets shut off.

Sterile skimmed milk has been found to be the best medium in which to suspend the bacteria. Overnight cultures of organisms are made and the growth is made into a semi-solid emulsion by adding a small amount of milk. Work during the whole operation should be carried out under sterile conditions lest the cultures should get contaminated. With a sterile capillary pipette about 0.2 c.cm. of the thick emulsion is introduced in each container which is immediately attached to the rubber tube after duly flaming the mouth of the ampoule and the tip of the rubber tubing. Any number of containers can be attached in this way. It is the general practice here not to use more than 24 tubes at one sitting. It becomes cumbersome to use more tubes and also the chances of leakage of air into the system become greater. The degassing self-freezing procedure is employed. Preliminary degassing is accomplished by reducing the pressure slowly and allowing the system to remain under this low pressure for about half an hour. Further reduction of pressure is obtained up to the point where frothing just begins to occur. This accelerates the degassing process. Consequent on the rapid evaporation taking place from the material the temperature of the substance falls and freezing sets in with a suddenness very much like the sudden crystallization of supersaturated solutions. In this manner, the advantages of rapid freezing are obtained without the use of refrigerants, such as dry ice bath with alcohol, ethyl, acetone, etc. When degassing is complete and the material is frozen, the pump is allowed to evacuate to the limit of its capacity. By the time the frozen material has reached the fusion temperature, the air pressure is reduced to such an extent that moisture is taken up by the drierite with sufficient rapidity to maintain the material in the frozen state. Drying from the

frozen state has been found to be complete in 4 to 6 hours, when not more than 0.2 c.cm. of the bacterial emulsion is used for each container. The time required, of course, varies with the thickness of the layer of material in the container and with the nature of the material itself. It may be advisable to allow determination of the residual moisture content by the method described by Flosdorf and Webster (1937) to decide the duration of processing. If sufficient drying time is allowed, the final moisture can be reduced to less than 0.1 per cent which corresponds to 99.9 per cent removal of the original water.

Evacuation is carried out to the limit of the capacity of the pump. Occasionally it happens that the pressure does not fall to the proper level, and in that event search should be made for leaks in the containers and container assemblies. A defective container is either sealed off or otherwise removed. After proper pressure is obtained, the apparatus requires no further attention until desiccation is complete, other than occasional inspection to see that the motor does not get too hot and to insure against failure of the electric power, etc. While drying

specimens of vaccinia virus the apparatus has been allowed to run overnight, much in excess of the minimal requirements, without any trouble.

After drying is complete, the containers are sealed individually without breaking the original vacuum and properly labelled. Before releasing for storage, it would be advantageous to test these

containers with a spark coil vacuum tester to ensure retention of vacuum. If the coil is made to touch the outside of the tube, a violet glow will appear in the tube if the vacuum is satisfactory. If there is a leakage, air and moisture get in with consequent deterioration or complete loss of viability of the bacteria. The ampoules are preserved in the cold room though our observations indicate that preservation at room temperature, at least for six months, does not materially affect viability. Flosdorf observed that the duration of activity of the dried material

at room temperature from 0°C. to 5°C., storage for long intervals should be at refrigerator temperature.

At the time when the product is to be used,

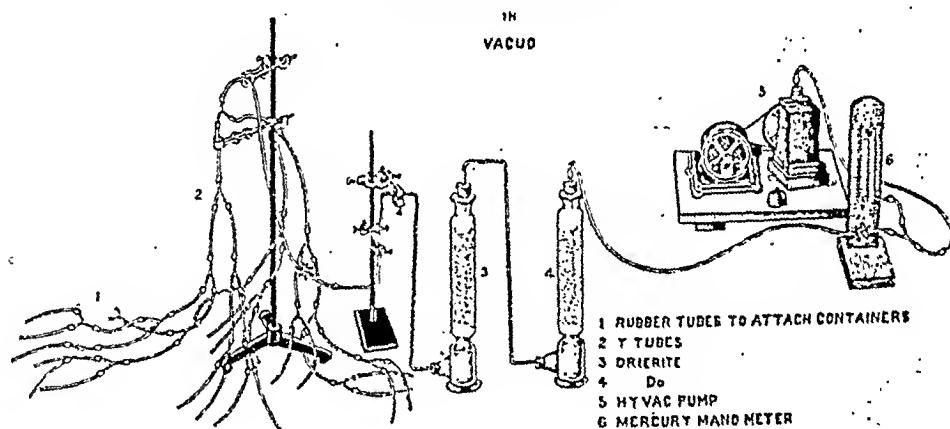

one of the ampoules is broken, the dried material emulsified in a little nutrient broth and then inoculated in suitable media and incubated. Invariably abundant growth takes place in 24 to 48 hours, the colonies appearing quite smooth.

The longest period for which the test has been done so far in this laboratory was ten months and tests covering longer periods are being made. It has been noted that the contents of an occasional tube, when tested, failed to grow on subculture. It is believed that this was due to defective sealing of the container which permitted the entry of air and with it aqueous vapour. The spark coil vacuum testing obviates this possibility.

This procedure has been adopted in maintaining experimentally a wide range of organisms, including such delicate bacteria as the *Neisseria gonorrhoea*, *Neisseria meningitidis*, *Hæmophilus influenzae*, *Hæmophilus pertussis*, etc. The viability of the organisms was tested at various intervals of time. A table showing the organisms tested and the longest period they have been found to survive is appended.

Clearly, this method of preserving micro-organisms provides a means of preserving bacterial cultures at low cost. There is considerable elimination of time and labour and expense of medium involved in constant subculturing. Storage and distribution to other laboratories

APPARATUS FOR DRYING BACTERIAL CULTURES SERUMIC

are very much facilitated. Furthermore, this method minimizes the tendency towards bacterial variation and impairment of antigenic capacity often encountered in laboratory subcultures.

Summary

The procedure and apparatus for preservation of bacterial cultures have been described in detail. The degassing self-freezing technique is employed by making use of a cheap desiccant (anhydrous calcium sulphate). No dry ice or any other refrigerant is used. The product obtained in this way by rapid freezing and rapid dehydration is sealed in glass ampoules *in vacuo* and stored.

ON THE COMPOSITION OF BUFFALO
MILK AND THE DETECTION OF
ADULTERATED SAMPLES PASSED AS
COW MILK*

By N. K. GHOSH, M.B., D.P.H., D.T.M.
and

B. K. DATTA ROY, M.Sc.

(*Provincial Public Health Laboratory, Shillong*).

ANALYSES performed in the laboratory for the purpose of the Assam Pure Food Act, 1932, have shown that samples of buffalo milk which contain a comparatively higher amount of fat and solids-not-fat are sometimes skilfully adulterated and sold as cow's milk, maintaining the standards (minimum for cow's milk, specific gravity 1028 at 15.5°C., fat 3.5 per cent and solids-not-fat 8.5 per cent) within the legal limit.

To devise a suitable method for the detection of such adulteration, a detailed investigation of the composition of a number of genuine samples of buffalo and cow milk had to be undertaken.

* Received for publication on 12th July, 1940.

* Not in author's typescript; supplied by editorial staff of the *Indian Medical Gazette*.

Altogether 613 samples of milk were analysed, of these 382 were cow milk and 231 buffalo milk. The majority of these samples were obtained from Government cattle farms in this province (Assam) and the rest were procured from animals milked in the presence of health officers or sanitary inspectors from different places in the province. All samples were obtained by mixing the complete yield of the animal and no foremilk was sent for examination.

In this note we have tabulated some of the results of analysis and have shown that the fat and the solids-not-fat in many samples of buffalo milk are such that these can be easily adulterated and passed as genuine cow milk within the legal limit, but the lactose content of the buffalo and the cow milk varies within a similar and narrow range, and, therefore, the estimation of lactose facilitates the detection of such adulteration, when water alone has been used as the adulterant.

1. Specific gravity of buffalo milk

The specific gravity of 231 samples of buffalo milk determined by the lactometer varied from 1028 to 1040 at 15.5°C. The present legal standard for buffalo milk as prescribed for the Assam Pure Food Act, 1932, is a minimum of 1028 at 15.5°C. No sample was found below this limit.

2. Fat percentage in buffalo milk

Fat was estimated by Gerber's method.

TABLE I
Fat content of buffalo milk

Fat, per cent	Number of observation	Percentage of total samples analysed
* 2.0	1	0.43
3.0	2	0.86
3.5	3	1.30
4.0	3	1.30
4.5	4	1.74
5.0	22	9.52
5.5	17	7.36
6.0	23	9.96
6.5	43	18.61

* Each figure in the first column of Table I includes ± 0.25 per cent of the milk constituent under consideration.

Table I shows that a considerable number of samples of buffalo milk examined had a fat

content of 5 per cent or above, but below the legal limit of 6 per cent.

As the milk samples examined during the present investigation sometimes include more than one sample from the same buffalo (particularly in the case of the buffaloes belonging to a Government Cattle Farm), the following table has been prepared to show that such samples of milk (with fat content below 6 per cent) were obtained from different animals and that the other constituents were within the legal limit (specific gravity 1028, solids-not-fat 9 per cent).

4. Lactose in buffalo milk

For rapid estimation of lactose in milk, the method described by Ghosh and Datta Roy (1940) was adopted.

Most of the samples examined were formalized milk, so the efficiency of formalin preservation of milk for the purpose of lactose estimation was verified and it was found that 3 drops (0.15 c.cm.) of formalin (40 per cent by volume) when added to 6 ounces of milk and placed in a corked phial preserved milk samples for 12 days without causing any significant deterioration in the lactose content.

5. The freezing point of milk

The freezing point is the most constant property of milk. Freezing points of a few samples

of buffalo milk were determined following the work of Andrew (1929), with the help of the simple form of Beckmann's freezing point apparatus, but anomalous results were obtained. Later, it was found that the varying results were due to the addition of formalin as a preservative. All the samples of buffalo milk had to be brought to the laboratory from distant places and no opportunity was found to study the effect of formalin on fresh buffalo milk.

The following study was made on fresh milk obtained from a cow kept under our observation, which will be mentioned in table VI as laboratory cow milk.

TABLE VI

The effect of addition of formalin on the freezing point of milk

Description of milk	Formalin, 40 per cent	Freezing point
Laboratory cow milk		- 0.550°C.
Milk 2 ounces ..	2 drops (0.1 c.c.m.)	- 0.580°C.
" 2 "	4 " (0.2 c.c.m.)	- 0.600°C.
" 2 "	6 " (0.3 c.c.m.)	- 0.640°C.

From the above table it will be seen that the addition of formalin causes a considerable

shift in the freezing point. It is evident that the dilution of buffalo milk with water or starch emulsion (in practice, the dishonest vendor often uses the supernatant water from boiled rice) may be carried out in such a way that the specific gravity, fat, and solids-not-fat remain within the minimum standards : 1028, 3.5 per cent and 8.5 per cent respectively prescribed for genuine cow milk. But the range of lactose content of the buffalo and the cow milk being almost the same (*vide* tables IV and V), such dilution or adulteration of the buffalo milk, if it is to be made profitable, brings the lactose value below 3.8 to 4 per cent, the minimum value for genuine cow milk obtained by us. Of course, if the adulteration be slight only, the estimation of lactose will not help to detect it. In preparing adulterated samples within legal standards for cow milk, the only difficulty occurred regarding the proper adjustment of the specific gravity, otherwise about 50 per cent of the samples of buffalo milk analysed (to a limit of solids-not-fat 11 per cent and fat 7 per cent) by us could be very profitably adulterated and passed as genuine cow milk. Cane sugar, starch solution, or rice-water can be detected in milk by very easy tests, but the detection of adulteration becomes difficult when the buffalo milk has been diluted with water only. In such cases of adulteration, the estimation of lactose will be useful.

Description of buffalo milk	Details of adulteration	ANALYSIS OF THE ADULTERATED MILK			
		Specific gravity	Fat	Solids-not- fat	Lactose
Shillong 'Pooled'	Milk 3 parts + water 2 parts + sugar	1028	3.5	8.5	2.48

Dibrugarh No. 2 ..	Milk 5 parts + supernatant water from boiled rice 2 parts.	1030	6.7	9.3	3.60

shifting of the freezing point. The determination of the freezing point is unsuitable for routine estimation of the specimens of milk, which generally are sent to the public analyst after formalin has been added as a preservative.

6. Detection of adulterated buffalo milk passed as cow milk

Analyses which have been described above show that in genuine buffalo milk the specific gravity may be as high as 1040, fat 12 per cent and solids-not-fat 15.5 per cent. A fat content of 8 to 10 per cent and solids-not-fat 11 to 13 per cent are common in the buffalo milk of Assam. It has been shown in the following

Discussion

The Assam Pure Food Act, 1932, and the Food Acts in force in Calcutta and Bengal and Bihar and Orissa demand that a genuine sample of buffalo milk should contain a minimum specific gravity 1028 at 15.5°C., solids-not-fat 9 per cent and fat 6 per cent.

From the analysis of 231 samples of genuine buffalo milk which have been recorded here, it appears that the minimum specific gravity and the solids-not-fat demanded are quite reasonable. But 22.51 per cent of the samples of milk analysed (table I) fall below the limit of 6 per cent fat content. If however the minimum standard for fat is reduced to 5 per cent

only 5.62 per cent of the samples remain below the limit. Table II shows that, at least in Assam, many samples of genuine milk from buffalo may contain as low as 5 per cent fat, and, if a sample of cow milk containing 3.5 per cent fat can be legally allowed to be sold as wholesome food, there is no reason why from the nutritional point of view, samples of genuine buffalo milk containing 5 per cent fat and satisfying other standards should not be legally considered as a pure food.

From the analysis of 218 samples of genuine buffalo milk it has been found that the range of lactose varies from a minimum of 4 per cent to a maximum of 5.3 per cent, whereas in cow milk (382 samples analysed) the range is from 3.8 to 5.3 per cent; only 2.67 per cent of the samples of cow milk analysed showed a lactose content lower than 4 per cent. During the progress of this enquiry it has been repeatedly observed that the fat content of the milk samples from an individual buffalo or cow varied from day to day within a wide range, but the lactose content remained fairly constant. Further, it has been found that in the majority of the samples of buffalo milk, which showed a high fat content (7 per cent or more), the lactose value generally was 4 to 4.8 per cent. Many of the samples which showed a higher lactose content (4.9 per cent or higher) often contained 6 per cent or less fat and were not suitable for dilution for the purpose of passing as cow milk.

At present, no standard for lactose is prescribed for buffalo or cow milk in the Assam Pure Food Act. It is suggested that at least in those provinces where the supply of buffalo milk is abundant and adulterated buffalo milk is sold as cow milk (which always fetches a better return) a minimum standard of 4 per cent lactose should be imposed for both cow and buffalo milk for the purpose of pure food acts. It has been proved from table VII that the dilution of buffalo milk containing a high amount of fat and solids-not-fat, if it is to be made profitable, brings down the lactose content lower than 4 per cent.

According to the Bengal Food Act, a minimum lactose content of 4.4 per cent and the specific

gravity between 1028 and 1030 at 15.5°C. are demanded for both cow and buffalo milk. We have found that for the province of Assam at least, a minimum of 4.4 per cent lactose content will be too high and a minimum of 4 per cent is recommended as a suitable one for both cow and buffalo milk.

As regards specific gravity we have observed that in many samples of genuine cow and buffalo milk the specific gravity exceeds 1030, for buffalo milk it may go up to 1040 and for cow milk to 1039; a minimum of 1028 specific gravity as demanded by the Assam Pure Food Act, for both cow and buffalo milk, is quite reasonable.

Our thanks are due to Lieut.-Colonel A. M. V. Hesterlow, I.M.S., Director of Public Health, Assam, for his permission to publish this paper.

Our thanks are due to Mr. R. C. Woodford, Deputy Director of Agricultural Live-Stock, Assam, for facilities rendered to obtain genuine samples of milk from Government Cattle Farms, to the Health Officers and Sanitary Inspectors especially to Dr. J. M. Roy of the Silchar Municipality, for their co-operation in conducting this work during the enquiry on the detection of adulteration of foodstuffs, under the Indian Research Fund Association.

Summary

Detailed analysis of 231 samples of buffalo milk and the lactose content of 382 samples of cow milk have been recorded. It is suggested that a minimum of 6 per cent fat for genuine buffalo milk demanded by some of the Pure Food Acts should be modified to 5 per cent and a lactose standard of 4 per cent (minimum) should be enforced for both buffalo and cow milk. It has been shown that the estimation of lactose facilitates the detection of diluted buffalo milk sold as cow milk.

A Mirror of Hospital Practice

A CASE OF ACUTE THROMBOCYTOPENIC PURPURA

By L. EVERARD NAPIER, F.R.C.P. (Lond.)
and

C. R. DAS GUPTA, M.B. (Cal.), D.T.M.
(From the School of Tropical Medicine, Calcutta)

THE patient, a boy aged 9 years, was admitted into the Sir John Anderson block of the Medical College Hospitals, under Dr. P. N. Ray, as a case of cellulitis of the face.

On re-examination, it was found that the condition was due to a subcutaneous haemorrhage which gave a peculiar purple colour to the skin over the tissues. Dr. Ray asked us to see the patient, we agreed to take him over, and he was subsequently transferred to the Carmichael Hospital for Tropical Diseases as a suitable case for investigation.

History.—The boy, the only child of young healthy parents, became suddenly ill about 10 days ago in his native village in Barisal. The illness started with a sudden high rise of temperature with definite chill. The

right side of the face began to swell; at first only the right cheek was swollen, but the swelling rapidly extended both upwards and downwards, and in the course of 3 to 4 days the whole face from the forehead down to the chin became a swollen purple mass. The village doctor diagnosed the case as cellulitis of the face and sent him down to Calcutta.

The boy had never had any serious illness before this.

Family history.—There was nothing unusual.

On examination.—He was quite intelligent for his age. He was of average height and of slight build. He looked definitely anaemic.

At first, both sides of the face were swollen (figure 1) and the appearance was that of cellulitis, but it was more purple than red, it was not hot, and there was

Fig. 1.

no real evidence of inflammation at the time we first saw the patient.—The condition was more or less confined to the face, from the hair margin on the forehead to the fold of the neck. Later, it spread further

Fig. 2.

down the neck and on to the chest and shoulder of the right side. After some time the left side of the face became normal, and the swelling and discolouration were essentially confined to the right side. On the nose

and upper lip there was a fairly sharp line of demarcation at the middle of the body, but on the neck the condition extended beyond the middle line. The whole area was dark purple in colour; it did not pit like oedematous tissue, but was spongy; gentle pressure caused a considerable flattening of the swelling, which immediately re-assumed its previous size and shape when the pressure was released. There was apparently a condition like a cavernous angioma which was emptied by pressure, but refilled rapidly. The skin of the lower part of the face and neck became thick and brawny, and the elephantoid condition of one side of the face pushed the nose over to the opposite side (figure 2). The right eye was kept closed the whole time he was in hospital, and with difficulty one saw the cornea which apparently remained quite healthy, probably because of the careful nursing. He had a low intermittent fever, nearly the whole time he was in hospital.

The spleen was enlarged—about 2 inches below the costal margin—and was soft; the liver was just palpable.

Nothing abnormal was found in any other organ and there was no pain or swelling in any of the joints. A few purpuric patches appeared from time to time on his lower limbs, but these could usually be associated with slight trauma.

Laboratory findings on admission

Hæmoglobin	..	4.67 gm. per 100 c.c.m.
Red blood cells	..	1,460,000 per c.mm.
Reticulocytes	..	12.7 per cent.
Mean corpuscular volume	102.7 cu. μ .	
Mean corpuscular hæmo-globin.	32.0 yy.	
Mean corpuscular hæmo-globin concentration.	31.1 per cent.	
White blood cells	..	18,850 per c.mm. Per cent Per c.mm.
Neutrophils	..	62 11,687
Lymphocytes	..	33 6,220
Large monocytes	..	5 943
Eosinophils	..	0 Nil
Abnormal cells	..	Two neutrophil myelocytes and twelve normoblasts per 100 white blood cells.
Van-den-Bergh test	..	Direct—negative; indirect 2.25 mgm. per 100 c.c.m.
Platelets	..	1,460 per c.cm.
Coagulation time	..	Three minutes (capillary tube method).
Bleeding time	..	Ten minutes (Duke's method).
Capillary resistance test (sphygmomanometer method).	..	Positive, i.e., decreased resistance of capillaries.
Prothrombin time	..	Twenty seconds (Quick's method).

Treatment and progress.—The boy was bleeding slowly but constantly, and this we thought to be the cause of the anaemia, so our first aim in treating the patient was to stop the bleeding, and to raise the number of circulating platelets. With these objects in view, we applied locally various haemostatics one after another; these included iron, alum, snake venom, and whole normal blood; each of these stopped the bleeding, but only temporarily. Together with the local haemostatics, 12 injections of vitamin C were given in doses of 200 mgm., some intravenously and others intramuscularly, also three injections of coagulin (Ciba) and two of haemoplasmin were given with temporary stoppage of the bleeding but without any improvement in the platelet count. Two injections of Russell's viper venom were given but these caused severe reactions and were therefore not repeated.

Transfusion of 250 cubic centimetres of fresh citrated blood was given on 18th February from a donor of the same group. This improved the anaemia slightly, but did not check the bleeding nor did it help to raise the platelet count.

The splenic enlargement had disappeared quite early. In spite of the various treatments given, the ecchymosis had extended for a short distance laterally to the other side of the face, and just across the middle line, upwards to the scalp and also downwards to the chest in the middle line.

Having failed to stop the haemorrhage, we turned our attention to treating the anaemia with the hope that improvement of the anaemia might lead to stoppage of the bleeding as well.

Ferrous sulphate, in doses of 12 grains a day, was therefore given for 21 days, from 21st March to 11th April, 1940. This improved the blood picture and the number of circulating platelets was raised considerably, though the number was still under the critical level (60,000 per c.mm.).

By this time, the blood was slowly absorbed from under the scalp and the left side of the face, and, by the end of May, the swelling under the scalp and the left side of the face had disappeared, the boy had greatly improved in health and the blood picture had also improved, but the platelet count was again going down and he was still bleeding from the mouth.

Deep x-ray therapy was now tried. Altogether three courses of deep therapy were given at the Calcutta Medical College. On each occasion exposures were given on three different areas over the spleen, in cyclical rotation in doses of 68r every day.

In the first course, from 31st May to 14th June, 1940, altogether 12 exposures were given over the three different areas in rotation, so that each of the three areas had 4 exposures of 68r. This seemed to have slightly improved both the blood picture and the platelet count.

A second course of iron was now given from 18th June to 9th July, 1940. There was slight improvement in the haemoglobin but both the red cell count and the platelet count fell, the latter quite appreciably. A second course of deep therapy was then given.

In the second course, 11th July to 18th July, only six exposures were given, so that each of the three areas had two exposures of 68r. After the second course, there was a marked improvement in the blood picture, and the platelet count went up considerably, though it was still below the critical level of 60,000 per c.mm.

As we had managed to raise the blood level to a point which would allow an operation, we recommended

so that each area had three exposures of 68r. During the third course of deep x-ray therapy, the haemoglobin red cell and platelet counts came down appreciably, and so further deep-ray exposures over the spleen were not given.

Our subsequent treatment was not based on scientific reasoning but was purely empirical. Though the prothrombin time was well within normal limits, three injections of vitamin K (Kapilin) 5 mgm. each day for three days were given, but without any beneficial result.

A few days later vitamin P was given in the form of Hespiridin (Lilly), 2 tabs. twice daily, from 14th September to 30th September. This too failed to effect any improvement. Finally, five injections of Lilly's concentrated liver extract 2 c.c.m. daily for five days were given. The patient was now going down, both in general health and in his blood picture. The father was again urged to allow splenectomy, but he refused and removed the boy (and incidentally most of the case notes) from the hospital.

Comment.—The ease reported above is undoubtedly one of acute essential thrombocytopenia, both clinically and haematologically. It fulfilled four out of the five points laid down as characteristic of the disease, *viz* :—

- (i) Reduced platelet count below 60,000 per c.mm.
- (ii) Decreased capillary resistance.
- (iii) Normal coagulation time.
- (iv) Increased bleeding time.

The fifth characteristic point, *viz*, that of the failure of the blood clot to retract normally, was not investigated.

Though there could be no question regarding the diagnosis, we do not feel that the whole clinical picture could be explained on the grounds of essential thrombocytopenia alone. It seems probable that the original diagnosis of cellulitis was correct and that this was complicated by the haemorrhagic diathesis. The angiomatic condition was probably due to a venous thrombosis and the elephantoid condition to some lymphatic obstruction which were the result of the original inflammatory condition. It was possible that a low-grade inflammatory condition still persisted. Even if we had been able to improve the thrombocytopenic condition, it seems very improbable that much improvement would have taken place in the local condition without some plastic operative procedure.

Splenectomy is the only procedure that is likely to improve essential thrombocytopenia, and this the patient's guardians refused to allow.

The haemorrhages in essential thrombocytopenic purpura vary directly with the number of platelets in the circulation—the fewer the platelets the more severe are the haemorrhages, and haemorrhage is rarely seen when the number of platelets is above 60,000 per c.mm. (Minot, 1917).

Thrombocytopenia is apparently due to defective formation, or defective maturation, of

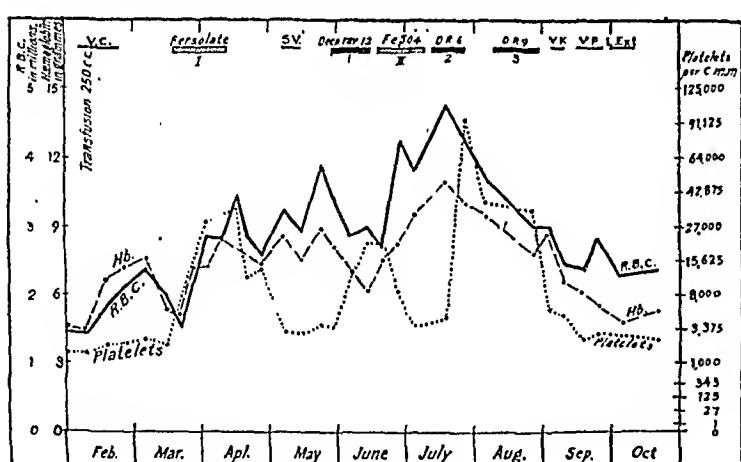

Fig. 3.—Progress chart.

V.C. = vitamin C.

V.K. = vitamin K.

V.P. = vitamin P.

D.R. = deep rays.

S.V. = snake venom.

removal of the spleen, but the patient's guardian refused.

After an interval of about a month a third course of deep rays was given, from 15th August to 29th August. In the third course, nine exposures were given,

the platelets at their site of origin, or to increased destruction in the spleen; these three factors may act singly or in combination. Examination of smears obtained by sternal biopsy gives some information about the formation and maturation of the platelets, but, although sternum puncture is done as a routine measure in all cases of anaemia and blood diseases under our care, we did not venture to do the operation on this boy because, as we have already stated, he used to bleed, sometimes for a long time, on the slightest prick. Thus we have no indication whether there was any defect in the formation or maturation of the platelets. Neither can we say whether excessive destruction of the platelets by the spleen was the cause of thrombocytopenia. For, though deep therapy was applied over the spleen, it was not sufficient to put the spleen out of action altogether, and the crucial test of splenectomy could not be done, as the relatives did not agree to any operative treatment.

Summary.—A case of acute essential thrombocytopenia is described in which the platelet count could not be raised above the critical level and the bleeding could not be stopped by haemostatics, serum, vitamins, or by deep x-ray therapy over the spleen.

RECOVERY FROM PNEUMOCOCCAL MENINGITIS TREATED WITH M. & B. 693

By SOHAN SINGH, M.B., B.S., F.C.M.S.

Second Physician to the Medical Out- and In-Patients,
Irwin Hospital, New Delhi

and

R. K. SEN, M.B., B.S.
House Physician

BEFORE the advent of chemotherapeutic treatment of pneumococcal meningitis with M. & B. 693 tablets, the prognosis in this disease was hopeless—once the case was diagnosed as pneumococcal meningitis, not even the remotest chance of its recovery was there. Ever since M. & B. 693 came to occupy the place it now does in the treatment of lobar pneumonia, hopes were aroused regarding the treatment of pneumococcal meningitis with the same drug. Lately, in the literature some recoveries from this dreaded disease, treated with M. & B. 693, have been reported. We have treated, in hospital and private practice, over a dozen and a half cases of pneumococcal meningitis with M. & B. 693 without a single recovery. We had, naturally, become rather sceptical about these reports and accepted them only with great reserve. This month, we have had two successful cases in the ward, and, since such a happy result is, as yet, far from being a common experience, we think it worth while bringing it to the notice of the profession.

Case 1.—A male, aged 17, admitted to the Irwin Hospital in the afternoon of the 10th February, 1941, in a delirious condition.

History.—Patient is a hawker by occupation. On the 9th instant, he suddenly fell ill with high fever, severe headache and generalized pain in the body. He very soon became delirious and markedly excitable. He had been like that till admission into the hospital. No past history of any kind was obtainable.

Examination.—On admission the patient was markedly delirious and showed signs of meningeal irritation. There was some rigidity of the neck muscles and Kernig's sign was positive. No abnormal signs were detected in the heart, lungs and abdomen. Temperature 99°F. in axilla. Pulse 120 per minute. Respiration 28 per minute.

A lumbar puncture was done immediately on admission and 20 c.c.m. of an opalescent fluid were drawn out. Fluid was under moderate tension. There was no relief in symptoms after lumbar puncture. The cerebro-spinal fluid was examined immediately and the report is as follows:—Turbid, deposits present, protein increased, large number of polymorphonuclear leucocytes and very few Gram-positive diplococci morphologically resembling pneumococci.

Blood examination.—Haemoglobin 55 per cent. Total leucocytes 12,500 per c.c.m. of blood. Polymorphonuclears 77 per cent, lymphocyte 17 per cent, large mononuclears 4 per cent.

Progress.—10th February. Lumbar puncture findings referred to above. Since M. & B. 693 was not available, only symptomatic treatment was given.

11th February. Temperature 100°F. General condition same. Lumbar puncture was done in the morning and 50 c.c.m. of turbid fluid was drawn out. Dr. H. R. Bhamboi, bacteriologist to the Irwin Hospital, very kindly supplied us with 25 tablets of M. & B. 693 for this case. The tablets were given as follows:—

4 tablets to start with,
4 tablets after 4 hours,
and then 2 tablets every 4 hours.

Morphine was needed for delirium, and retention of urine was relieved by catheter.

12th February. General condition better. Still some headache. Temperature came down to 96°F. Pulse 100 per minute. Lumbar puncture: 25 c.c.m. of fluid taken out. Fluid still not clear.

14th February. General condition better. Had good sleep. Temperature subnormal. Lumbar puncture: 15 c.c.m. of clear fluid drawn out.

15th February. Lumbar puncture: 15 c.c.m. of clear fluid. Examination showed very scanty Gram-positive diplococci.

16th February. Lumbar puncture: 5 c.c.m. of clear fluid.

17th February. Lumbar puncture: 2 c.c.m. of clear fluid. Examination showed no pneumococci.

18th February. General condition good. Temperature 98.4°F. Lumbar puncture omitted.

19th February. Patient discharged as cured.

Case 2.—A girl, aged 16, admitted into the Irwin Hospital at 1 a.m. on the 17th February, 1941, with headache, fever and pain on movement, in the neck muscles.

History.—The illness started with headache and fever on the 15th evening. The headache became very intense in the evening of the 16th and led to the suspicion of meningitis.

Examination.—Patient looked seriously ill and was restless and somewhat delirious. No neck retraction was seen. Lungs, heart and abdomen showed no abnormality; Kernig's sign was positive.

Lumbar puncture: Cerebro-spinal fluid turbid and under tension. About 30 c.c.m. came out. No relief in symptoms after it. Examination of the fluid revealed presence of pus cells and Gram-positive diplococci, morphologically resembling pneumococci.

Patient was put on M. & B. 693 tablets. Dosage same as in case 1.

Progress.—17th February. Temperature 103°F. Pulse 135 per minute, respiration 24 per minute. Lumbar puncture findings referred to above. Night passed badly

with little sleep. Lumbar puncture was repeated at 11 a.m. Only about 2 c.cm. of turbid fluid came out. Throughout the day the patient was restless and delirious. Hypnotics had very little effect. Temperature in the evening 102°F., pulse 125 per minute.

18th February. General condition better. Headache very much less. Some delirium still present. Morning temperature 101.8°F., evening temperature 98.4°F. Pulse also came down to 96 per minute in the evening. Lumbar puncture was done at 11 a.m. but only about 2 c.cm. of turbid fluid came out. Examination still revealed pus cells and pneumococci. Patient vomited M. & B. 693 tablets once.

19th February. General condition much better. No headache. Temperature subnormal. Pulse 95 per minute. Patient had good sleep at night. Feeling of marked asthenia. Lumbar puncture omitted.

20th February. General condition good. Patient desirous of going home. Lumbar puncture: 2 c.cm. of clear fluid under normal tension. Examination revealed no pneumococci.

21st February. Patient discharged cured.

Conclusion

Two cases of pneumococcal meningitis successfully treated with M. & B. 693 are reported. M. & B. 693 has come to occupy an important place in the treatment of lobar pneumonia and other pneumococcal infections in the body. Its success in pneumococcal meningitis is a great advance in the treatment of this disease. Why the drug succeeds in some cases and not in others will be elucidated as time passes and more and more case reports become available so as to find out the factors which are responsible for its not being uniformly successful.

My thanks are due to Lieut.-Colonel M. M. Cruickshank, chief medical officer, Delhi, for his kind permission to report these cases, and to R. S. Dr. H. R. Bhamboi for his generosity in supplying M. & B. 693 tablets for one case.

DACTYLOMEGALY : A CASE NOTE

By WALTER BRINITZER

Bangalore

THE case described is one of a continued growth of the bones of the right hand.

Family history.—Health and longevity are the outstanding features. Father and mother died aged 99 and 80 respectively. Six brothers and sisters—5 died aged 70, 65, 60, 55 and 44 respectively. One alive and well, aged 65. Twelve children—4 died in childhood of typhoid and small-pox; 8 alive and healthy. The family history reveals no cases of tumours, malformations, or chronic ill-health.

Personal history.—The patient, a man aged 60, was born in Bangalore and never left Mysore state except for a holiday to Delhi. He states that when he was 19 he had an attack of bubonic plague affecting the cervical glands of the right side. This did not accelerate the growth. Apart from this he gives no history of illness.

As long as he can remember he has had the deformity (figures 1 and 2). At first this consisted of only a slight thickening and lengthening of the right thumb and forefinger, but throughout his life it has continued to grow. At 25 his hand was about half its present size. At 45 the middle finger started growing. Until he was 50 he could eat with his right hand. From

boyhood he learned to use his left hand for all practical purposes and he dresses and helps himself in every way with it. He can write Kanarese, Hindi and Marathi fluently.

Fig. 1.

Measurements.—The circumference of the right forefinger (9½ inches) is the same as that of the left (healthy) upper arm. Its length (13 inches) is 2 inches

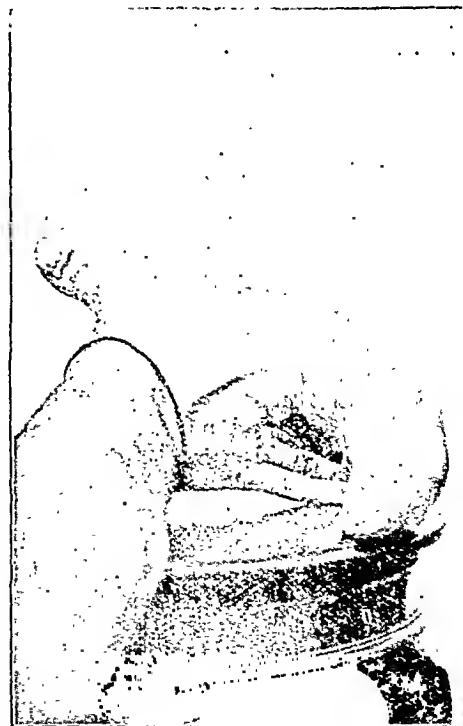

Fig. 2.

more than that of the left forearm. The circumference of his right thumb is 7 inches, which is 4 inches more than that of the normal left wrist. The thumb is half

the length of the forearm. The corresponding measurements in inches on the two sides are:—

	Right	Left
Circumference of wrist 11	$6\frac{1}{2}$
Circumference of forearm 12	9
Circumference of upper arm 11	$9\frac{1}{2}$
Length of forearm 12	11
Length of upper arm 14	14

Examination.—In the right extremity the colour and thickness of the skin and the distribution of hair appear normal, and it receives an undiminished blood supply. The nails however show trophic changes. The secretions, sweat and sebum are produced in normal quantities. All sensory impulses are carried normally. No active or passive movements of the thumb and forefinger are possible. There is slight mobility of the middle finger. Motor function of the right little finger is unimpaired. The right forearm shows a subcutaneous lipoma. Due to the heavy weight of the right extremity and the desire to avoid unnecessary movements there is wasting of the biceps, infraspinatus and teres major muscles.

X-ray.—In the hand (figure 3) the first and second metacarpal bones are enlarged and thickened. There

Fig. 3.

is extensive proliferation of bone in the phalangeal joints. No joint spaces in between the phalanges are seen, as there is bony ankylosis. The phalanges are also enlarged and thickened. There is extra bone formation on the medial side of the first, second and third phalanx near the joint. In the wrist the carpal bones are not individually distinguished from one another, as there is proliferation of bones and bony ankylosis. In the forearm the radius shows thickening at its middle. Exostoses are seen in connection with the upper end of the radius.

General examination.—There is no other abnormality. Heart and lungs are normal, liver and spleen not palpable, reflexes present, genital organs normally developed, no changes in bones and joints, apart from his right arm. He does not even show any signs of senility (arcus senilis, atrophy of the skin, etc.), his mind is active and he takes a keen interest in various subjects. All his teeth except two are well preserved. The urine shows no albumin, sugar or urobilinogen. My first impression was that it might be a case of elephantiasis, but there was no evidence of filarial infection.

Discussion.—If we consider malformations such as congenital dislocation of the hip, club hand and club foot, webbed fingers and other congenital deformities, in most cases we are as ignorant of the ultimate cause as of the cause of tumour growth. The relations between tumours

and malformations are very intimate, and it is hard to draw a dividing line between them. The classification of tumours is based on the type of tissue and mode of growth rather than on their aetiology, if we define a tumour as a mass of tissue growing without any regard to the laws which govern and restrain the growth of normal tissue. Gigantism, partial or universal, falls in the same group.

We understand that the complicated structure of bone is extremely sensitive to disturbances of metabolism. We know the rôle of phosphorus, calcium and magnesium salts and vitamins in certain bony alterations. We have some knowledge of the influence of hormones on the growth of bone. We know about the disturbance in calcium metabolism through loss of the parathyroid. The chromaffin system, the ovaries and testes, the thymus and hypophysis also play an important part in bone formation and growth. In acromegaly we happen to know the cause of the excessive growth, namely hyperplasia or increased activity of the anterior lobe of the pituitary gland; the bones as well as the soft parts of the face, hands and feet become greatly thickened.

In hypertrophic pulmonary osteo-arthropathy, which results in elongation of the bones of the extremities, the new bone formation is supposed to be due to the absorption of some toxic substance, since it accompanies chronic lung diseases.

Apart from the malformation described above in detail, a lipoma and exostoses are present. Is the existence of three different kinds of tumours on the same extremity a mere coincidence? Exostoses are sharp outgrowths from the surface of a bone, usually recognized to be the results of fractures or of some inflammatory disease. But how are we to explain their frequent occurrence in one family and in cases where the history does not reveal injury or inflammation?

In the growth under discussion probably its cell structure is less abnormal than its excessive vigour of growth. The balance of growth between various tissues is maintained by a higher law which we cannot understand.

I am indebted to Dr. Jayaram, radiologist, Bowring and Lady Curzon Hospitals, for the X-ray examination and the report on it.

A CASE OF DYSTROPHIA ADIPOSO-GENITALIS

By BANSIBAT DUTTA, M.B.

Howrah

S. K. M., Bengalee, Hindu, male, aged 17 years, came under my treatment on the 11th March, 1938, with the following complaints:

(i) Gradual increase in weight, (ii) deposition of excessive fat, (iii) somnolence, and (iv) mental deficiency.

All these complaints began to manifest themselves about three years ago.

Previous history.—Patient suffered from chronic tonsillitis about five years ago for which the tonsils were removed. He was having nocturnal enuresis since early boyhood.

Physical examination.—The patient had a round face with double chin (see figure 1). There was no hair in the axillæ, pubic region and on the face. There

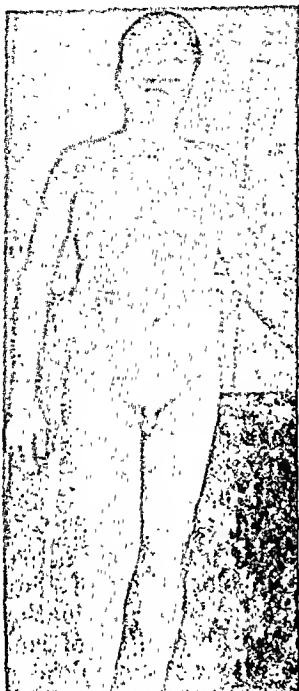

Fig. 1.—Before treatment.

was deposit of excessive fat on the breasts, anterior abdominal wall and the buttocks, which made his appearance rather feminine. The external genitals were rudimentary. The penis measured 3 cm. in length and was about the girth of the tip of the little finger. On the left side there was a small soft testis in the scrotum about the size of a pea with testicular sensation. On the right side, however, there was no testis and no sensation. The subcutaneous inguinal ring on the right side was smaller than that on the left. The height of the boy was 58½ inches. The chest and abdomen measured 33 and 34 inches, respectively, and the weight was 120 pounds.

Provisional diagnosis.—Dystrophy adiposo-genitalis.

Treatment.—The patient was given extract thyroid siccum, half a grain twice a day on empty stomach and Lugol's iodine solution, five minimis twice daily, and he was kept on a diet with restriction of fat and carbohydrates. He had also milk and banana diet once a week and complete fasting once a week. Parenteral administration of the gonadotrophic hormone from the anterior pituitary given every other day with increasing doses of the thyroid extract for a month and a half produced the following improvements:—The right testis descended into the right side of the scrotum, the latter becoming more roomy. Testicular sensation was present but the gland was very soft. The left one became bigger; the size was nearing that of an adult. The penis was enlarged and resembled that of an adult in shape. The hairs in the pubic region started developing. The height increased to sixty-one inches (gain in height—2½ inches), but the weight of the patient was reduced by three pounds.

The same treatment was continued, only the dose of thyroid extract was increased gradually till 4th May. It was now that the patient developed polyuria (12 to 15 times daily), the total quantity amounting to 85/90 ounces a day. The urine was examined and a

skiagram of the base of the skull was taken. The urine did not contain any sugar and the skiagram showed no abnormality of the sella turcica and the anterior and posterior clinoid processes, so that any congenital tumour of the pituitary body could be excluded.

The patient was given whole pituitrin—0.5 to 1 c.c.m. every other day in place of the anterior pituitary hormone for three weeks. The polyuria disappeared.

From the 10th July an intensive course of treatment followed—anterior pituitary hormone 2 c.c.m. every other day with thyroid extract, two grains twice a day for a fortnight with milk and banana diet only. There was further improvement as shown in figure 2.

Fig. 2.—After treatment.

19th July. The dose of thyroid was increased up to seven grains daily and anterior pituitary hormone 2 c.c.m. on alternate days was continued up to 11th September. The following results were noted:—Height 62½ inches (total increase 3½ inches), weight—106 pounds (total loss 14 pounds); penis—adult shape, partial retraction of foreskin, 4½ inches long. Testis—both descended, adult size and consistency, the right being smaller than the left. Face—masculine; voice—peculiarly masculine with marked personality. Hairs developed on face, axillæ and pubic region; mental condition improved. On prostatic massage and milking the urethra a little prostatic fluid was obtained.

The patient was not willing to undergo any further treatment. However, he was advised to report bi-weekly. On 5th July, 1939, the seminal fluid showed a few motile sperm cells on microscopic examination. Thereafter, the patient underwent no further treatment. The height was 64½ inches.

Points of interest in this case are:—

1. A case of this type is rarely encountered in this country.

2. It is very difficult to increase the dose of thyroid extract without estimation of basal metabolism rate. I had to stop or lessen the dose owing to the appearance of toxic symptoms, e.g., tremor, tachycardia, etc. However, it is an interesting fact that the patient could tolerate seven grains daily.

3. According to some reports the treatment is very likely to be unsuccessful in patients aged more than 10½ years owing to the fact that the testes lose the function of spermatogenesis if they are retained inside the abdomen for a long time. But this particular case has more than proved the efficacy of treatment even after this age.

Indian Medical Gazette

MAY

THE TREATMENT OF BURNS

It is surprising that the treatment for such an everyday domestic accident as a burn should have gone through so many changes in so short a time, yet, since the beginning of the century, the changes have been numerous and revolutionary; backward steps appear to have been taken now and then, but on the whole the progress has been forward. Some readers will perhaps remember the carrom-oil period of which we still see traces in out-of-date books on first aid and domestic remedies. As we grew more sepsis-conscious this phase was followed by those of the antiseptic ointment, and then the dry dressing with the pain and tissue destruction that the usually-frequent dressings involved; this brought us to what was probably the most disastrous of all, the picric-acid dressing, which was the first-aid dressing during the last war. The only thing that could be said in favour of picric acid was that it had a slight tanning effect, but removal of the dressing often converted a first-degree into a second-degree burn, and, further, a considerable percentage of individuals were extremely susceptible to picric-acid poisoning; when this fact was once established, for several months every medical journal one picked up reported some disaster following often a simple burn, until it was recognized that this once-popular form of treatment amounted almost to malpraxis.

Wars have a stimulating effect on the study of traumatic surgery; it was not however a war, but industry that gave us the most notable recent advance: tannic acid came out of the Ford factory, literally as well as metaphorically, and it has held the field almost unchallenged for 15 years. With the present war, a slight reaction has set in, the extreme virtues of tannic acid are being questioned, some surgeons are going as far as stating that it should never be used on the face, hands, or even feet—but there is far from a general agreement on the point—and tannic acid is being supplemented and in some instances replaced by silver nitrate (10 per cent) and the dyes, gentian violet and brilliant green.

We must not however lay too much emphasis on one aspect of this subject only, for, though the first-aid dressing and the first surgical dressing are important, we must remember that it is the patient and not the burn that has the first claim to attention.

Shock.—It is usual to divide the shock into primary and secondary. Though this division is probably real enough, it is not one of very great practical importance. So-called primary shock is mainly psychological, and due to pain

and fear; it is likely to be less marked in the tough soldier than in the better educated officer, who knows the dangers associated with a severe burn, or in the civilian. There is also a neurogenic factor, as noxious stimuli to the skin are known to cause vasodilation, and, in practice, patients with extensive superficial burns suffer more primary shock than those with more limited deep burns. Of individuals dying from burns the death from primary shock is placed as low as 2 per cent. Primary shock will be at its height within the first two hours and the treatment is warmth and morphia, of the latter a liberal dose of a third of a grain for an adult is necessary. This initial dose of morphia is indicated even after the stage of primary shock and particularly when a patient has been travelling for some time and is badly in need of sleep. The warmth can be provided in the ways that circumstances dictate, from electric blankets to the more primitive bottles of hot water for external application, and by hot drinks or even hot coffee enemata where burns on the face and mouth make drinking painful.

It is secondary shock that claims most of the deaths due to burns, and the figure is placed as high as 80 per cent; the causes of this shock come into operation as early as two hours after the burn and operate for some considerable time, but are probably at their height within the first 48 hours. The causes, which are entirely different from those of primary shock, are the absorption of histamine-like substances from the damaged tissues and loss of plasma which exudes from the damaged surface; both tend to produce the same result, loss of plasma from the circulation, a concentration of red cells especially in the peripheral capillaries, a decrease of blood volume, and a fall of blood pressure. The tannic acid treatment is aimed at limiting the effect of both these causes, preventing the absorption of toxic substances by coagulating the surface protein, and preventing the exudation of plasma through the impermeable covering that is thus produced. In a severe burn the haematocrit reading may rise from the normal of about 48 per cent to 80 per cent; this means that there has been an effective loss of well over fifty per cent of the plasma, which represents a much higher actual loss, because there will have been considerable replacement from the tissues; this replacement will have had the effect of lowering the plasma protein. There is also an increase of plasma potassium. As red blood corpuscles are already in embarrassing excess, transfusion of whole blood is not indicated, nor, on the other hand, is saline transfusion, as this would lead to a further dilution of the plasma and lowering of the plasma protein. Therefore, at this stage plasma transfusions should be given, if this substance is available; if not, 6 per cent gum saline is the best substitute. Plasma transfusions present considerably fewer difficulties than do those of whole blood, for, if it is separated early, plasma

keeps for a considerable time in the fluid state, and it can be dried and preserved almost indefinitely in powder form. The other advantage is that, though grouping is necessary, the chances of obtaining a suitable plasma for a person of any particular group are much greater, for the plasma of an AB individual can be given to anyone, an O individual can take plasma of any group, and by suitable mixing of blood specimens any plasma can be made safe. Other measures to be adopted are the intravenous administration of suprarenal cortical extract or the synthetic product desoxycorticosterone acetate in full doses, to raise the blood pressure and reduce the plasma potassium. Finally, in cases of profound shock oxygen should also be given by some adequate means (and not by waving a glass funnel some inches away from the patient's face).

Toxæmia.—This is the next danger to which the patient is subjected, and it may come into action any time after forty-eight hours. Even in cases in which there is no sepsis there may be a considerable degree of toxæmia from the absorption of the damaged tissues, and in this tannic acid will have a considerable limiting effect. If to this sepsis is added, the toxæmia may be considerable. Tannic acid applied as a first-aid measure under favourable circumstances may prevent this occurring, but as a general rule the freedom from sepsis will depend on the first treatment that the patient receives at the surgeon's hands and on subsequent nursing. Here chemotherapy is claimed by some as an invaluable adjuvant, whereas others give it little place.

Scarring and contractures.—In severe burns some scarring is inevitable, but the final result will often depend to a large extent on the early treatment. It is in this connexion that tannic acid has recently come in for some severe criticism. Examples have been exhibited of crippled hands with necrosed terminal phalanges and scarred faces with ectropion, resulting, it is claimed, from the injudicious use of tannic acid. It is perfectly comprehensible that, in the case of the digits, an inelastic circle of tanned tissue might lead to oedema and eventually seriously interfere with the blood supply, but one must obviously be careful not to blame the tannic acid when it was really the original burn that caused the damage. As far as the face is concerned the eyelids should certainly not be included in the tan mask.

First-aid.—This will consist firstly in the prevention and treatment of the primary shock, a reassuring word to the nervous subject, a warm stimulating drink such as hot coffee, protection from cold, and an injection of morphia if the pain is severe. If there is likely to be any delay in getting the patient to hospital or other place where proper surgical treatment can be carried out, some form of first-aid dressing must be applied. What this

should be will often be a matter that is decided by what is available; the choice lies between 2 per cent tannic acid, 1 per cent aqueous solution of gentian violet, and tannic acid jelly. If the delay is likely to be long the coagulating tannic acid preparations are indicated, but if short the dye is preferable. Gauze is soaked in the tannic acid or dye solution and applied in a thick layer to the burnt area.

Surgical treatment.—Again shock must be given the first consideration; the badly shocked patient should receive a plasma transfusion of at least 500 c.cm. and other methods of countering shock should be applied before anything else is done. The blood pressure is the best indication of the degree of shock and of the amount of plasma loss that has to be replaced. If a burn is at all severe, an anaesthetic will be essential. Gas and oxygen anaesthesia is probably the best, but if the face is badly burnt this may be difficult, and some intravenous anaesthetic such as pentothal, up to a maximum 0.5 gramme in divided doses as the cleaning-up progresses; for the depressing effect of these intravenous anaesthetics is against their general use in cases of extensive burns; in cases where this dosage does not produce sufficiently prolonged anaesthesia, after the face has been dealt with it can be covered with gauze and the anaesthesia continued with gas and oxygen.

The whole burnt area and the surrounding skin should be cleaned with saline, soap, or if absolutely necessary ether soap can be used provided the area is washed well with saline immediately afterwards, but as a general rule antiseptics should be avoided. The treated areas are covered with a saline pack for five minutes or so, and then swabbed or sprayed with some aqueous dye solution; the best preparation is the triple dye solution—2.5 grammes of gentian violet and brilliant green and one gramme of flavine to a litre. The area is dried rapidly, if possible with an electric hair drier, and then a coagulant preparation applied. The orthodox procedure is to spray the area every half hour with a 5 per cent solution of tannic acid over a period of ten hours, but such a procedure will often put too much of a strain on the nursing staff and is further very disturbing to the patient. An alternative is to produce an immediate tanning by dabbing on a 5 per cent solution of tannic acid and 10 per cent silver nitrate alternately, until a firm tan has been produced.

There is, as we have said above, a school of thought that deprecates the use of tanning substance on the face and hands; if the whole face is burnt the eyelids should be smeared with vaseline and covered with two or three thicknesses of lint while the rest of the face is being treated, either by 5 per cent tannic acid, or simply with saline packs and dyes, if one prefers to forego the advantages of tanning in order to obviate possible dangers of subsequent

scarring, which many surgeons do not think are very real. The triple dye alone will produce a fine supple coagulum and this should perhaps be the treatment of choice for the digits.

The greatest danger of subsequent infection comes from cracks in the tan and from the junction of the sound skin with the tan covering. For this reason the edges should be well painted with the dye solution referred to above or with a 1 per cent solution of brilliant green in 30 per cent alcohol, and if there is any sign of moisture at the edges the painting should be repeated frequently. Cracks should be treated in the same way. After the tan has dried, a light dry dressing is applied and it may add to the comfort of the patient to lay the limbs on splints and bandage them lightly. The area should be inspected daily, but should not be interfered with unless the patient shows signs of toxæmia; the tan will usually separate in from ten to fourteen days.

On the place of the sulphanilamides in the treatment of burns, opinions are again divided, but the balance of opinion is in favour of their routine use. The usual dosage is employed, an initial dose of three tablets, followed by two tablets four hourly for 48 hours and one tablet four hourly for another 48 hours. Powdered sulphanilamide is also recommended for the tan-skin junctions and cracks in the tan whenever there is any sign of sepsis, or even as a routine prophylactic measure. One objection that is raised to the use of sulphanilamides is that a nourishing diet is important and that eggs are a useful item in such a diet. A liberal diet with plenty of protein is certainly essential, but for this purpose milk is preferable to eggs. Diet is undoubtedly an important factor; it should include plenty of protein to replace the lost plasma protein and the full complement of vitamins.

Subsequent treatment.—In the burns of the first and second degrees, after the tan separates the delicate underlying skin will require some care and it should be protected and kept soft by rubbing well with lanoline. In third degree burns the best dressing is vaseline gauze which should be kept on for another fortnight until the area is covered with healthy granulation tissue.

The subsequent treatment of the severe burn is the field of the plastic surgeon, but it should be remembered that directly the area is covered by granulation tissue skin grafting should be undertaken, or scarring and contractures will be inevitable.

HÆMATOLOGICAL TECHNIQUE

In the past, the attitude of the medical profession in India towards anæmia has been that it was an almost inevitable accompaniment of residence in a tropical country, and that therefore *per se* it need not claim attention. It is now beginning to be realized that when a patient is anæmic there is always some pathological process to account for the fact, and that, whilst other methods of ascertaining the nature of these pathological processes should not be neglected, much information may be obtained from the blood picture. Consequently, far more attention is being paid to anæmia itself, and the importance of accurate methods of blood examination for the proper study of a case of anæmia is gradually being appreciated.

Many books on laboratory technique give full details of all the various methods that can be adopted, but such books are not always within the reach of practitioners: further, the methods described in these books are often embarrassing in their multiplicity. We therefore felt that a series of articles on hæmatological technique would be of some practical use to readers of the *Indian Medical Gazette*, particularly those working in India. The first of these articles appeared in our February number last year, and the eleventh and last appears in the present number.

These articles describe the methods that are used at the Calcutta School of Tropical Medicine. Whilst in a few of them there are original modifications, for the most part the methods described have been well tried by workers in other countries and are accepted as accurate; in every instance, those given have been the routine methods at the School of Tropical Medicine for some considerable time, in most instances for years, and are considered by the authors to be the methods of choice for Indian conditions.

It is proposed to issue these as a series of collected papers. The booklet should be ready for issue in June. A strictly limited number only will be available, so that an early application to the publishers* is recommended.

There is also a proposal that these articles on technique should be included in a Government of India publication on anæmia of pregnancy which will be issued later this year. As the object of this publication is to ensure uniformity in procedure in different laboratories in India, in order to facilitate comparison of results obtained in different parts of the country, the authors would welcome criticisms or suggestions by others who have had practical experience of hæmatological methods, now, so that, if they think it desirable, they may add to or modify the descriptions of technique before the final proof of this second publication goes to press.

*The distributing agents for the publishers are Messrs. Thacker, Spink and Co. (1933), Ltd., 3, Esplanade East, Calcutta. The book, about 180 pages, bound in full cloth, with two coloured plates, will be sold at Rs. 3/-, inclusive of postage in India.

HÆMATOLOGICAL TECHNIQUE

PART XI

By L. EVERARD NAPIER, F.R.C.P. (Lond.)

and

P. C. SEN GUPTA, M.B. (Cal.)

(From the School of Tropical Medicine, Calcutta)

Red cell diameters : Price-Jones curve

Introduction.—In the normal blood, the red cells are not all exactly the same size, but in no individual cell does the size deviate very much from the mean. However, in some forms of anaemia the mean size of the red cells is much below the 'normal' mean; in others, it is far above it. But, in the latter case, there are nearly always some exceptionally small cells as well, so that the picture presented is that of cells of a great range of different sizes. This blood picture is best presented in the form of a curve, the abscissa being the size and the ordinates the number of times that cells of the particular size have been encountered (*i.e.*, the frequency). In the normal count, the curve rises sharply from the base line at about 6.0μ to a peak at 7.25μ and then falls almost to the base line again at 8.50μ . This graph is usually known as a Price-Jones curve. In the normal individual the shape of the curve is more constant than the mean diameter of the cells, which in a group of individuals will vary within, but rarely fall outside, the range 6.7μ to 7.8μ .

Price-Jones calculated what he called 'ideal' maximum and minimum normal curves (Price-Jones, 1933).

In different forms of anaemia this curve will vary in shape, its median will move to the right or to the left, and it may be of the normal height, or flatter than normal.

These variations in the curve can be expressed in figures. The median can be given in terms of microns, but it is more usual to give the mean corpuscular diameter (MCD), also in microns; the flatness of the curve is shown by the standard deviation (σ) of the diameters of the cells from the mean diameter, or more accurately by the co-efficient of variation (v), and also by the percentage microcytosis and macrocytosis. These data can all be calculated from the Price-Jones curve.

The measurement of cell volume percentage and calculation of the mean corpuscular volume (MCV) has been described already in an earlier paper in this series; this MCV gives the volume of the cells but not their diameter. Further, it is a 'mean' measurement and from it one gets no idea of the range of size of the individual cells; it is therefore more limited in its application than the Price-Jones curve.

Neither measurement, however, alone will give information on the thickness of the cells, but this can be calculated from the MCV and MCD. The method of making these calculations will be described later.

The technique of the measurement of cell diameters.—The technique described below is a modification of Hynes and Martin's method of measurement of red cell diameters.

The images of the cells are projected on the vertical ground-glass screen of a Bausch and Lomb euscope, at a magnification of 2,000, and the measurements are made with the help of a celluloid protractor on which a series of circles, with diameters increasing by the equivalent of 0.25μ , have been drawn.

Apparatus required

- (i) A Bausch and Lomb euscope with projection screen.
- (ii) A mechanical-feed arc lamp with condenser, working at 4.5 amperes.
- (iii) A glass container filled with distilled water for cooling the beam of light from the arc lamp (filter).
- (iv) A microscope with oil-immersion objective and eye-piece to give a magnification of 2,000 on the projection screen of the euscope.
- (v) A stage micrometer scale (Zeiss) with divisions 10μ apart.
- (vi) A celluloid cm./mm. scale.
- (vii) Celluloid protractor for measuring the cells (*v.i.*).

Preparing the celluloid protractor.—At a magnification of 2,000, 1μ corresponds to 2 mm. and 0.25μ to 0.5 mm. The circles on the protractor are drawn with diameters increasing by the equivalent of 0.25μ (0.5 mm.), *i.e.*, the radii of the circles increase by 0.25 mm. The measurements of the radii of the series of circles are best obtained from a diagonal scale drawn to give measurements in multiples of 0.25 mm.

The circles are drawn in Indian ink with very fine bow-pen compasses on a celluloid sheet, with radii increasing from 4 mm. to 12 mm. by steps of 0.25 mm., so as to give measurements corresponding to 4μ to 12μ diameter. Circles smaller and larger than the above are drawn on another sheet. The first sheet is generally sufficient for routine work; the second is needed very exceptionally (see figure 1).

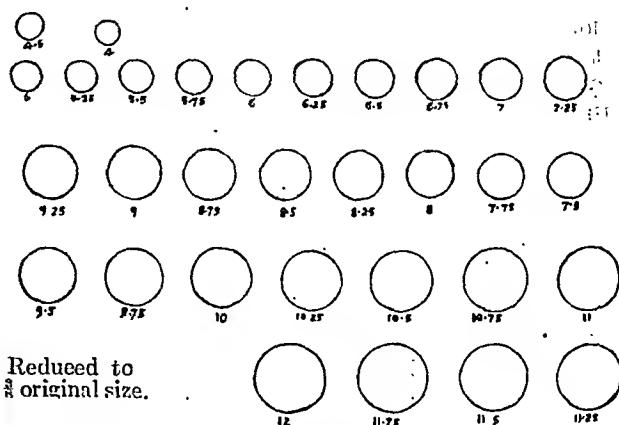

Fig. 1.

Assembling and adjusting the apparatus.—Figure 2 shows the euscope with microscope

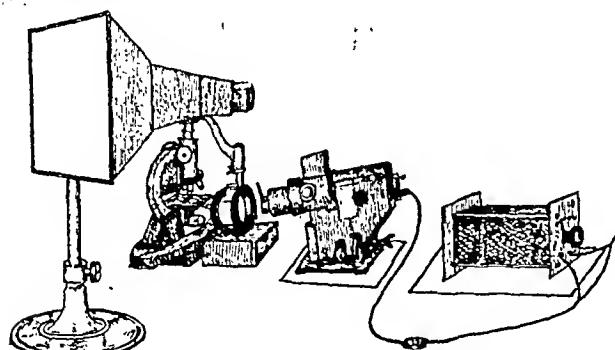

Fig. 2.

and arc lamp assembled. The concentrated beam of light from the arc lamp, cooled by passage through water in the filter, is focused on to the *concave* mirror of the microscope which reflects it through the condenser, the objective, and the eye-piece of the microscope. The total reflexion prism of the euscope placed over the ocular reflects the light on to the opaque screen of the euscope. The condenser is fully raised up, and, with the high power objective turned on, a bright beam of light is focused on the opaque screen. After the illumination has been adjusted the micrometer scale is placed under the objective of the microscope and the image of the scale is focused on the opaque screen, first using the low power and finally the oil-immersion objective. A final adjustment of light is made to give the maximum illumination. The opaque screen is now moved off and the image is focused on to the ground-glass projection screen of the euscope. By moving the microscope and/or the prism, the image of the scale is so projected that the lines of the scale are vertical, parallel and entirely free from spherical aberration, at least within an area of about 4 inches by 3 inches marked out around the centre of the viewing screen.

That there is no spherical aberration within this area can be shown by noting that the distances between the images of the lines are the same in all parts of this area. The magnification of the apparatus is adjusted to be 2,000 by using a suitable oil-immersion objective and eye-piece, and varying the length of the draw-tube of the microscope. [A Zeiss microscope with objective 90, and a Leitz eye-piece 15 \times , with a draw-tube length of 154 mm. gives a magnification of 2,000 on the projection screen of the particular euscope used in our laboratory.]

To find the magnification the distance between the images of two lines of the scale is measured with the celluloid cm./mm. scale and, at a magnification of 2,000, the images of the lines of the scale are 2 cm. apart (2 cm. = 20,000 μ). [If the different components of the apparatus are kept fixed after the above adjustments, the measurements can be carried out

without repeating these adjustments every time.]

Measuring the cells.—The micrometer scale is next removed, the blood film, stained with a Romanowsky stain and counter stained with 1 per cent aqueous eosin solution, is placed under the oil-immersion objective, and the image of the cell is focused on the ground-glass screen of the euscope. Only those images of the cells that fall within the reduced field are measured. The celluloid protractor with the series of graduated circles is superimposed on the image of the corpuscles to find the circle that fits the image of each cell. Each cell is measured to the nearest 0.25 μ . The measurement of circular corpuscles is quite easy. In the case of the irregular-shaped corpuscles, a circle is found such that the area of the corpuscle falling outside the circle is about the same as the area of the circle unfilled by the image of the corpuscle (see figure 3). Five hundred cells are measured

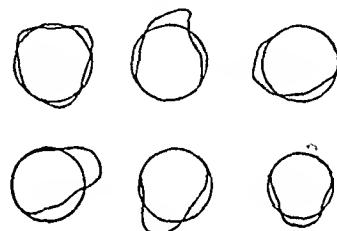

Fig. 3.

from different parts of the blood film. It is better to avoid the 'tail' end and the thick parts of the smear, as in the former the cells are excessively spread out and in the latter the cells overlap and are not well spread.

Recording the results.—By this method, 500 cells can be measured in about 40 to 90 minutes, the time depending on the size of the cells and the degree of poikilocytosis; the larger and more irregular the cells the longer is the time required. An assistant is needed to note down the measurements and record the number of cells counted with a counting machine of the type of a Veeder counter.

From the figures obtained, the mean diameter, standard deviation, and co-efficient of variation are calculated. A Price-Jones curve is drawn by plotting the figures on graph paper. The degree of microcytosis and macrocytosis can also be determined from this curve, by comparison with the maximum and minimum ideal curves; the overlapping of a curve beyond the minimum ideal curve on the low side and the maximum curve on the high side indicates the degree of microcytosis and macrocytosis, respectively.

Method of calculating.—The following figures show the method of calculating the mean cell diameter (MCD), the standard deviation, (σ), and the co-efficient of variation (v).

6.5 μ , the median, has been taken as the arbitrary mean.

TABLE I

Dia-meters in microns	Number of cor-puscles in each class (f)	Deviation (d) of each class from arb. mean, in 0.25μ , i.e., the class interval	$f \times d$	$f \times d^2$
5.25	4	-5	-20	100
5.50	18	-4	-72	288
5.75	34	-3	-102	306
6.00	67	-2	-134	268
6.25	74	-1	-74	74
6.50	107	0	-402	0
6.75	70	+1	+70	70
7.00	50	+2	+100	200
7.25	46	+3	+138	414
7.50	18	+4	+72	288
7.75	5	+5	+25	125
8.00	4	+6	+24	144
8.25	2	+7	+14	98
8.50	1	+8	+8	64
			+ 451	
	500		+ 49	2,439

n = total number of observations = sum of frequencies (f) = 500.

$\Sigma f d$ = sum (Σ) of the product of the frequencies (f) and the degrees of deviation (d) from the mean = + 49.

$\Sigma f d^2$ = sum of the product of the frequencies (f) and the squares of the deviations (d^2).

Class interval = 0.25μ .

Mean corpuscular diameter (MCD) =

$$\text{arbitrary mean} + \left(\frac{\Sigma f d}{n} \times \text{class interval} \right)$$

$$= 6.5 + \left(\frac{49}{500} \times 0.25 \right) \mu$$

$$= 6.5245 \mu.$$

$$\begin{aligned} \text{Standard deviation } (\sigma) &= \sqrt{\frac{\Sigma f d^2}{n} - \left(\frac{\Sigma f d}{n} \right)^2} \\ &\quad \times \text{class interval} \\ &= \sqrt{\frac{2439}{500} - \left(\frac{49}{500} \right)^2} \times 0.25 \mu \\ &= \sqrt{4.878 - (0.098)^2} \times 0.25 \mu \\ &= \sqrt{4.878 - 0.0096} \times 0.25 \mu \\ &= \sqrt{4.868} \times 0.25 \mu = 2.206 \times 0.25 \mu \\ &= 0.551 \mu \end{aligned}$$

$$\text{Co-efficient of variation } (v) = \frac{\sigma \times 100}{\text{MCD}} = \frac{0.551 \times 100}{6.525} = 8.4 \text{ per cent}$$

From the mean corpuscular diameter (MCD) and the mean corpuscular volume (*vide* part IV), the mean corpuscular average thickness (MCAT) can be calculated, by means of the following formula :—

$$\text{MCAT} = \frac{\text{MCV}}{\pi r^2} \mu = \frac{\text{MCV}}{\pi \left(\frac{(\text{MCD})}{2} \right)^2} \mu$$

Example.—

Let $90 \text{ cu. } \mu$ be the mean corpuscular volume (MCV) and 6.52μ the mean corpuscular diameter (MCD).

$$\text{Mean corpuscular average thickness (MCAT)} = \frac{90}{\pi \left(\frac{6.52}{2} \right)^2} \mu = \frac{90}{3.14 \times (3.26)^2} \mu = 2.69 \mu$$

The normal range of MCAT is from 1.7 to 2.5μ (Price-Jones, Vaughan and Goddard, quoted by Whitby and Britton, 1939).

In order to calculate the percentages of microcytosis and macrocytosis, it is necessary to have 'ideal' minimum and maximum curves for the population in which the investigations are being carried out. Price-Jones calculated the 'ideal curves' for subjects in Great Britain. Working on similar lines, we (Napier and Sen Gupta, 1941) have worked out two similar curves. Two smoothed curves are shown in figure 4 and the expected frequency distributions in the ideal minimum and maximum curves are given in table II.

To arrive at the percentage microcytosis and macrocytosis, the number of cells of each size (below 6.9μ), in excess of the number of that particular size that appear in the minimum ideal curve, are summed; this number divided by 5, to reduce it to a percentage, is the percentage microcytosis. Similarly, the number of cells of each size (above 7.8μ), in excess of the number of that particular size that appear in the maximum ideal curve, are summed and divided by

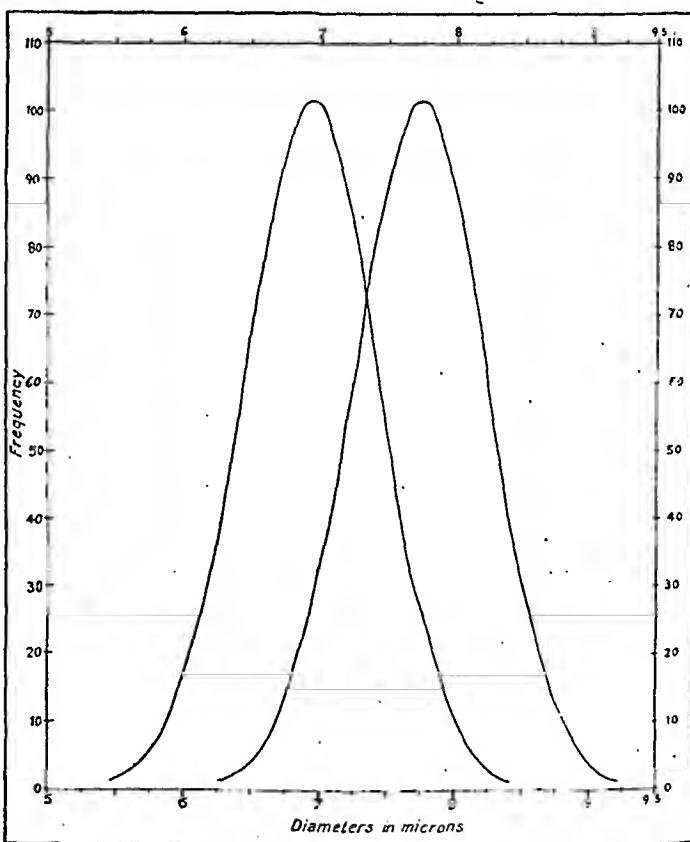

Fig. 4.—Ideal maximum and minimum curves based on Indian data (Napier and Sen Gupta, 1941).

5 to obtain the percentage macrocytosis (*vide* table II).

Significance of the findings.—It is not possible here to enter into any extensive discussion on

the significance of the different findings, but as a general rule it may be taken that in cases that have a high microcytosis percentage and a low MCV the anaemia is due to iron deficiency.

When such microcytosis is associated with a normal, or even a high MCV, it means that the cells are thicker than normal and there is a tendency to spherocytosis; such a condition is usually found in haemolytic anaemias. Pernicious anaemia shows a flat curve with a wide base, usually a high percentage of macrocytes and a few microcytes, whereas tropical macrocytic anaemia is usually associated with a moderately tall curve with an MCD slightly on the macrocytic side, a few macrocytes, and probably no microcytes.

SCHOOL MEDICAL INSPECTIONS*

By W. H. CRICHTON, C.I.E., M.B., CH.B., D.P.H.
 LIEUTENANT-COLONEL, I.M.S.

Chief Health Officer, Delhi Province, New Delhi

In a way I am glad that the title given to this talk has been that of 'School Medical Inspections', because it gives me the opportunity of laying stress on one of the main failings of the work which has been carried out hitherto in schools in India. It has been my experience to find that school schemes are all inspection and little or no treatment. In Delhi, even now, I regret to say a scheme of this sort is still in existence in the city, where two doctors are engaged by Government to devote their entire time to the examination of all school children—at least all the boys—in all the schools in turn, and to the lamentably unsuccessful task of attempting to interest their parents in their children's ailments. No sooner have they completed one round of this breathless task than they have to start all over again to cover the ground twice in each year. Like the painters of the Forth Bridge who, no sooner having completed their job, have to start again at the other end, these doctors have no time to do anything else for their charges, or to see whether the advice given by them has been carried out. In short, there is no 'follow up' and without effective 'follow up' the mere inspection of school children in this way can have no value at all, other than the collection of data for statistical purposes. The fault in the present system is due partly to misunderstanding of the function of a School Medical Service and partly to a failure in the adaptation of the school schemes on the British model to conditions prevailing in India where the proportion of physically defective children found on inspection is as high as 70 per cent among boys and 62.6 per cent among girls. In the School Medical Services in England, children with physical defects are specially re-examined by the school medical officer twice a year and more frequently if necessary, but the number of physically defective children found on inspection there is something of the order of 15 to 20 per cent as compared with over 70 per cent in India, and therefore what is possible in England is not possible out here.

Let us for a moment recall the system in vogue in England. There under the consolidating Education Act of 1921, a duty is imposed on the local education authorities to make arrangements for the medical inspection of school children attending public elementary schools 'on their admission and on such other occasions as the Minister of Health may direct'.

It also imposes the duty of making suitable arrangements for attending to the health and physical conditions of the children. For any treatment provided under these arrangements the parents must be charged, if their circumstances permit, but no obligation is imposed on the parent to submit his child to medical inspection or treatment. In the exercise of his powers under this Act, the Minister of Health has directed that in addition to an examination of the child on admission to school, there should be a full 'routine' examination of each child at 8, and again at 12, and thereafter annually in the higher schools up to the age of 17.

Thus, routine examinations are carried out only at intervals of 3 years and 4 years in the junior classes and only become an annual feature in the comparatively small higher classes. Compare this with the schemes in India where attempts have been made to conduct 'routine' examinations twice a year. This is obviously futile and I cannot help feeling that originally a misunderstanding must have occurred and that the biannual* re-examination of defective children was taken for the complete routine examinations referred to in the Education Act of Great Britain.

At the 'routine' medical examination in England, the parents' children are invited to attend and they are advised of the existence of any defects which may require treatment and told how best this can be obtained, either at a school clinic, or at a specialist's clinic appointed by the local authority for the purpose, or at a hospital, or by the child's own private medical practitioner. Thereafter, the children concerned are kept under regular medical supervision until the defects have been removed. In addition to this on the occasion on which the doctor (school medical officer) visits a school, he examines at the request of teachers or parents, any children which they may wish to refer to him on account of any physical or mental defects noticed by them.

My experience of the application of these principles to this country is that few if any parents will ever come to the school when the routine inspections are carried out, and that their interest in their children's ailments and their cure is not sustained. Also it is rare for the parent or teacher to refer any cases to the doctor on their own initiative, until the condition has progressed beyond the scope of the school medical officer. Apart therefore from informing the parents of the condition found and obtaining their consent to any treatment which may be required, it is impossible in India to rely on the parents to maintain their interest in their children's ailments. It is necessary therefore to arrange for the treatment and 'follow up' to be carried through the School Medical Service itself.

Nevertheless one should not be content with this arrangement. It should be recognized that the ultimate success of the school schemes based on these principles must depend on the active interest and collaboration of all the school staffs and parents. The school teaching staff in the course of their duties are afforded unrivalled opportunities of observing children's daily progress, both physical and mental, and so they are in an extremely favourable position to pick out such defects as they may develop at the earliest possible moment. If such cases are referred to the school medical officer at once and appropriate treatment instituted without delay the chances of the condition developing into serious proportions is minimized considerably.

The first duty of the school medical officer therefore must be that of establishing the most cordial relations with the school staff, to explain to them the nature and the function of a School Medical Service and to make them realize the very important part which they themselves have to play in making the service a success. Similarly the school medical officer should seek an opportunity to make similar contacts with the parents of the children for whom he is responsible and to explain to them also the functions of the

* As biannual means 'lasting for two years' or 'appearing every two years', that is, every alternate year, might not the misunderstanding also have arisen this way.—EDITOR, I. M. G.

service and the way in which they can be of invaluable assistance in the interest of their own children's health. What then are the functions of a School Medical Service?

- (i) Primarily, the School Medical Service is designed to provide the means for the early recognition of physical or developmental defects among school children;
- (ii) secondly, the School Medical Service should provide the facilities for the treatment of defects found, not only at a minor treatment clinic, but also by specialists, especially those in dentistry and ophthalmology, by hospitals or by medical practitioners;
- (iii) thirdly, the School Medical Service should furnish, either gratuitously or at reduced rates, the means for providing spectacles for children who cannot afford them;
- (iv) fourthly, the School Medical Service should include special schools or classes for backward children, for enfeebled children, for the blind, deaf, dumb, tuberculous, epileptic, crippled or debilitated children;
- (v) fifthly, the School Medical Service should include arrangements for the provision of additional meals (*e.g.*, milk) for ill-nourished children;
- (vi) sixthly, the School Medical Service should arrange for the protection of children and school staff against disease by vaccination and inoculation.

These arrangements demand the co-operative and co-ordinated effort of local administration in the health department, school medical officers, hospitals, specialists, school authorities, parents, and medical practitioners.

In addition to the organization and supervision of the Service on these lines, the school medical officer has other duties which are frequently forgotten, namely:—

- (i) He should advise on school closure when this is indicated by the outbreak of infectious disease;
- (ii) he should control the exclusion from school of cases of contacts of infectious disease, and pay home visits;
- (iii) he should ascertain through home visits the cause of absences, frequent or prolonged, of children from school and of recurring physical conditions which may be attributable to domestic circumstances;
- (iv) he should advise on the suitability of school premises, and on the adequacy of sanitary and drinking water arrangements;
- (v) he should be responsible for the lighting arrangements in class rooms, particularly on desks and black boards, both natural and artificial, and study their effect on the causation of eye strain;
- (vi) he should advise on school furniture and study the effect of such furniture (*i.e.*, desks) on posture;
- (vii) he should advise on the type and paper provided in textbooks used by the school children;
- (viii) he should advise on the schemes of physical exercise and on the organized games prescribed for the children;
- (ix) he should take a lively interest in the personal hygiene of the scholars and of the teachers.

The translation of these principles into practice is by no means always an easy matter. The main difficulty usually lies in the geographical position of the schools concerned. It would obviously not be economical to provide a clinic and a school medical officer for every little school. On the other hand, the maximum number of children which one school medical officer can reasonably be expected to look after cannot be more than 2,500.

An important practical point is that a scholastic year only gives one 190 working days on an average, and that there are only five working hours on each one of those days. Now with good organization the maximum

time for a 'routine' examination is ten minutes for an expert, and no school medical officer should be expected to carry out more than 15 routine examinations a day. Thus, 150 minutes or 2½ hours are taken up by routine examination leaving 2½ hours which should be devoted for the examination of referred cases and for the 'follow up' and treatment of those found physically defective. At this rate the maximum number of children a doctor can examine in one year is 2,850, but as we have seen the school medical officer has many other duties to attend to and it would be safer therefore in the interests of efficiency to aim at a maximum of 2,500.

Where the schools concerned happen to be large schools grouped closely together as is the case in the municipal boys and girls schools in New Delhi, the problem is very much simplified, because a central clinic can be provided for all the schools with a whole-time school medical officer in attendance. These are ideal conditions.

On the other hand, when the schools are scattered the problem is much more difficult of solution. The following alternatives are then open to us:—

- (a) The grouping of schools on a regional basis to be served by a clinic situated geographically as centrally as possible; or
- (b) the clinic-in-every-school system.

In the former system each school has a compounder in immediate charge of it and working under a school medical officer who goes round the schools in turn. The compounder is responsible for carrying out, at the clinic or at school if possible, the day-to-day minor treatment prescribed by the medical officer. 'Routine' examinations are carried out in each school itself so as to interfere as little as possible with school routine. The number of schools must be limited by the number of scholars and the S. M. O. must visit each one in turn at least once a week. A scheme on these lines is contemplated for 10 schools in Delhi City with a total population of nearly 20,000 pupils.

In the second system there is a small clinic or dispensary in each school and no central clinic. A nurse is employed to visit two schools every day and to carry out the minor treatments prescribed by the doctor, who, in turn, visits each school once a week. There is a scheme of this sort in existence in Delhi City. It is maintained by the Delhi Health Society, who serves 10 girls' schools with a total population of 2,470 children and costs Rs. 1,678 (*plus doctors' fees*).

One has to admit that the central clinic scheme, unless ideally situated relative to the schools, as it is in New Delhi, is not suited for girls in India and it is probable that there will be some difficulty about attendances at such clinics even in the case of the boys. This is one of the reasons for which the compounder is employed so that the scholars may be shepherded for treatment or examination. If the schools are not grouped conveniently together in the same compound, then the best system for a large number of girls' schools is the Delhi Health Society scheme I have described.

In the rural areas the problem presents even greater difficulties owing to the scattering of the schools, poor communications and inadequate staff. As things are, the doctors attached to rural dispensaries can only get round to each school about twice a year, or at best once a quarter. This is obviously not enough for either adequate supervision or care. The only hope therefore lies in the training of school teachers in the recognition and simple treatment of minor ailments by the use of first-aid boxes by suitable courses at normal teacher's training schools.

The Education Act in England demands that the parent pays for any treatment received if he can afford it. In India the principle is that 2 annas per head per scholar may be charged from scholars in the middle and higher schools or classes. Where primary education is not compulsory there is no legal objection to the fees being paid by children attending primary classes. I have little doubt however that it will be impossible to make a School Medical Service, properly organized and equipped, pay for itself at the rate of 2 annas per

head. But this fact need not deter any one. The local authority must be made to realize the importance of the School Medical Service as a means of ensuring the

health of their future citizens, and that authority should be prepared to bear such balance as may be required, as an insurance for the future health of the nation.

Medical News

ASSAM PROVINCIAL MEDICAL RESEARCH CONFERENCE

THE first annual Assam Provincial Medical Research Conference, held in Shillong on 31st March, was presided over by Dr. L. Everard Napier, Professor of Tropical Medicine at the Calcutta School of Tropical Medicine. Dr. Napier, in his opening address, gave a short account of the important medical research activities in Assam during the last 50 years.

A number of important papers were read at the conference; these included papers on typhus fever in Assam and the bacteriology of diarrhoea in Shillong by Captain Woodhead. The former disease was, he said, far more common than was usually suspected, and he added that the blood of all cases of doubtful fever should be sent to the Pasteur Institute for testing for typhus fever—this would be undertaken free of cost.

Dr. Viswanathan read three papers on malaria; the one that raised the greatest interest was on the control of malaria by spray-killing of adult mosquitoes. There are great possibilities in this measure for the individual protection of people living in highly malarious places.

Dr. Hare read an interesting paper on anaemia, and the chairman, Dr. Napier, concluded by giving details of a very important advance that has been made in the treatment of kala-azar, by means of a drug of entirely different composition from any that have previously been used in the treatment of this disease. He had treated, up to date, 30 cases with excellent results in each instance; many of these patients had hitherto proved resistant to treatment with ureastibamine and other antimony preparations.

This paper led to an interesting discussion, particularly on the question of urea-stibamine-resistant cases of kala-azar that have been reported in Assam. This drug seemed to provide a good answer to this problem.

At the conclusion of the conference, the chairman said that, as this first conference had been a great success, he hoped that it would be possible to hold such a conference each year. He suggested that a little earlier and wider publicity might be given for the conference next year.

The chairman's address

Dr. Napier, in his opening address, apologized for not presenting an address really worthy of the occasion, but explained that he had only been asked to take the chair since he had arrived in Shillong. Dr. G. C. Ramsay, who was to have presided, was unable to interrupt his tour programme. To give an adequate account of the medical research work that had been done in Assam, Dr. Napier said, it would be necessary to turn up the earlier volumes of the *Indian Medical Gazette*, the *Scientific Memoirs* of the Government of India, and other official publications that appeared before the *Indian Journal of Medical Research* and its offspring, the *Journal of the Malaria Institute of India*, but as he had neither the time nor the opportunity to do this he would have to speak from notes written from memory. He continued:

'Some of the earliest research work done in the province of Assam was in connection with kala-azar. In the eighteen nineties, the second great kala-azar epidemic occurred in Assam; its focal centre was Nowrang, a point which the previous epidemic had not reached. In those days nobody knew what the disease was—whether it was a severe form of malaria or a disease *per se*? The research giants of those days, Ross and Rogers, each came up to investigate it and each went away defeated. They both believed that it was a particular form of malaria.'

'Colonel Giles, an I. M. S. officer who also investigated the disease, thought that it was caused by hookworms, and Dr. Bentley, who was against the malaria theory, was misled by a positive agglutination test and suggested that it was a malignant form of Malta fever. Rogers with the help of Dodds-Price, whom many of you will remember, formulated measures of prevention which even to-day, with our knowledge of the way the disease is transmitted, are the only measures that one could suggest, namely, complete destruction of lincs and removal to a new site.'

'That epidemic subsided, leaving behind its trail of endemicity but no light as to the nature of the disease that had withdrawn itself. In 1903 the causative organism of kala-azar was discovered and in 1915 the first specific treatment for the disease was introduced; Rogers and Muir demonstrated its relative efficacy in Bengal and Dodds-Price in Assam, so that when the next epidemic started in 1917, this time higher up the valley in Sibsagar subdivision, we were at least armed with the knowledge of what the disease was and how it could be treated. But I must not concentrate on kala-azar.'

Pasteur Institute

'In 1916, an important event in the history of medical research in Assam occurred; the Pasteur Institute was opened. This event was an important one to me personally, because it gave me my first independent job in India and coincided with an important geographical discovery—I discovered that Shillong and Ceylon were two separate places and a long way from one another.'

'I was at the time understanding Captain Knowles (who had just returned from Mesopotamia where he had been wounded at the battle of Ctesephon) at the Cumbala War Hospital in Bombay, where he was bacteriologist. Knowles was selected as the first Director of the Pasteur Institute of Assam and some of you will perhaps remember the boundless energy that Knowles put into any job he undertook. War or no war, he managed to get that institute on a sound working basis, not only as a Pasteur Institute but as a research centre. Knowles remained in Shillong for nearly four years and was then selected by Sir Leonard Rogers to organize the School of Tropical Medicine in Calcutta.'

'The germ of the idea of starting such a school in the tropics originated in the mind of Dr. Winchester, a tea-estate medical officer whose name is still revered in Assam; once started in the mind of Sir Leonard Rogers, the idea materialized very rapidly. Rogers was, and still is, a fighter, and the official difficulties only stimulated him to greater efforts; but it was only through the help of the big European industries—tea, jute and mining—that he fought and eventually won over the officials and founded his school.'

'Rogers looked upon Assam as one of his main fields for clinical and other investigation and that tradition is still maintained at the school.'

'To return once more to kala-azar.'

Pre-antimony days

'Dr. Ramsay remarked at the annual general meeting of the British Medical Association last week that it was hard for the younger men coming out to practise in the tea districts to realize what conditions were like 28 years ago, when he first came out. He was not thinking of kala-azar, because he did not see it in his district. I admit that my association with Assam does not date back to the pre-antimony days, for I first

came to Assam in 1919, but I had plenty of opportunity of discussing the subject with men who had recently had the distressing experience of being powerless to do or suggest anything in the face of a diagnosis of the then fatal disease, kala-azar.

'To them, and to all of us in those days, the discovery of intravenous antimony tartrate seemed little short of a miracle. Yet a few years later, this same treatment had been put so far into the shade by the newer forms of treatment that it was almost looked upon as malpraxis to give the trivalent salts of antimony when one of the efficient pentavalent compounds was available.

'Though the organization for the wholesale treatment of kala-azar in Assam that undoubtedly helped to check the 1917 epidemic, originated by McCombie Young and Taylor, was based on the trivalent salts, the great success of this measure would never have been achieved without the brilliant chemotherapeutic investigations of Professor Hans Schmidt and his enterprising followers in this country, notably Sir U. N. Brahmachari. So much for the treatment of kala-azar and the part that Assam workers have played in establishing it, for the time being at any rate, as I shall have a little more to say on the subject during this morning.

Sandflies suspected

'The last epidemic of kala-azar was subsiding before we were able to get any definite information as to how the disease was transmitted from one person to another. Colonel F. P. Mackie who succeeded Knowles at the Pasteur Institute and had worked on kala-azar in Assam before the last war, always suspected sandflies, and as early as 1921, I remember helping him to catch, dissect, or rather squash, and examine many specimens in Nowgong, but we were unlucky, in that we were, I believe, only catching *Phlebotomus minutus*, a variety that lived mainly on lizards. The discovery of the development of leishmania in the silver-footed sandfly, *Phlebotomus argentipes*, was not made until three years later at the Calcutta School, mainly as a result of epidemiological investigations in Calcutta which showed that the disease was confined largely to one particular quarter of the town where conditions were particularly favourable for this sandfly and where we found it abounding.

'The kala-azar commission, under the auspices of the Indian Research Fund Association, followed this line of work and carried matters much further. The commission worked first at Golaghat and then at Gauhati under the directorship of Sir Rickard Christophers, Colonel Shortt, and, for about a year, myself, and eventually the remains of this commission, now lowered to the status of an enquiry, was transferred to Calcutta under my charge. When in 1934 the enquiry was eventually closed down, the position had been reached that kala-azar was almost certainly transmitted by the sandfly, *Phlebotomus argentipes*, but we had not found out the trick of how transmission could be effected with certainty. Many infected sandflies had been found in nature and a few infections had been transmitted to hamsters by the bite of this sandfly, but against this there were many failures, and the complete failure to transmit the disease to human volunteers.

Natural immunity

'Dr. R. O. A. Smith, who worked with us in Calcutta, has again taken up work during the last two years. Smith has a way with sandflies that nobody else seems to possess and he has now succeeded in making them transmit the infection almost at will; he has done this by giving the flies feeds, subsequent to the infecting feed, on fruit juice, so that the infection is not suppressed by subsequent blood meals; the fly becomes so heavily infected that it cannot suck blood properly, until it has, so to speak, coughed up a large plug of flagellates into the wound its proboscis has made.

'The conditions of this experimental transmission are such that would occur in nature, and I myself do not feel that that the human experiment is necessary

to complete the case against this sandfly; for man enjoys a high degree of natural immunity.

'The real problem is to devise means of controlling this sandfly in nature, and I am glad to be able to tell you that Dr. Smith is again coming to work in Assam on this very problem.

'The only further advance that I myself can visualize, except in the matter of sandfly control, is that it may be found that some special fruit or plant provides an exceptionally favourable meal for the sandfly, or exceptionally favourable medium for the growth of leishmania in the sandfly, and that the distribution of this plant, as well as that of the sandfly, may determine the distribution of kala-azar, for there are still some anomalies in this direction to be explained.

Malaria

'Whilst kala-azar was attracting the attention of the health authorities, the really far more serious disease, malaria, was being accepted as something that was inevitable. It was the tea-estate medical officers who first made a stand against this attitude.

'I won't attempt to recount the beginnings of anti-malaria work in Assam or to apportion the credit, but the name that sticks out in this connection is that of Dr. G. C. Ramsay, and nobody could deny that Dr. Ramsay with his dynamic personality has been, and to-day still is, the greatest enemy of the malaria-carrying mosquito in Assam—not to mention many other parts of India.

'As a tea-garden medical officer he introduced new principles into the subject of malaria control and put these principles into practice on his own gardens with the brilliant success that you all know, and since he joined the Ross Institute he has diffused his special knowledge and infused his enthusiasm throughout the tea districts in Assam and much further afield. No more fitting chairman could have been chosen for this Conference, and I feel that my occupation of this chair, through Dr. Ramsay's inability to interrupt his programme, is somewhat of anti-climax.

'In mentioning Dr. Ramsay in connection with anti-malarial work in Assam I know that I am on safe ground, but, even at the risk of omitting more important names, I do not feel that I can close this subject without mentioning the work of Manson at Cinnamara, Fraser at Labac, and Lamprell at Nazira, for with all three I am personally very well acquainted and at the headquarters of the two former I have spent many interesting weeks.

'Nor must I omit to mention Colonel Morison, whose efforts started the Assam Research Society, and Dr. Rice with his native hustle, whose work on malaria in particular did so much to justify this enterprise.

'The mention of Colonel Morison inevitably brings one to bacteriophage. Whether I am wise in mentioning this subject I do not know. I usually place bacteriophage with religion, as a dangerous subject of controversy, but it certainly had its day in Assam, as it has had nowhere else. Perhaps one day Colonel Morison will be hailed as prophet; perhaps not; history will decide.

Another great scourge

'After malaria, bowel diseases are Assam's greatest scourge, and this is a group of diseases in which the last twenty years has seen great changes occur, but not as a result of bacteriophage or any other form of treatment. The answers to this problem were known to us all; they were water supply and sanitation. In the gardens where a good water supply has been established, the battle has been half won; when a satisfactory latrine system has been established, bowel diseases will cease to be a serious problem. And with the bowel diseases hookworm infection will also go. Though I do not want to dwell on another of my pet subjects, I believe that the debilitating effect of hookworm anaemia is not sufficiently realized.

'The amount of valuable research work that has been done in Assam in the past is very considerable, and the opportunities for further research are enormous.

The microscope and the well-equipped laboratory are valuable tools for the research worker, but they are by no means essential. The basis of all research work is accurate records of observed facts, whether they are observed clinically or through the microscope. The inaccuracy of vital statistics in India is the greatest handicap to both research work and public health administration in this country. In tea-garden practice, there is a wonderful opportunity to supply this deficiency and I believe that Dr. Lamprell and those who have laboured at standardized returns for tea estates have done a great service, not only to the tea industry but to the province as a whole.

The genesis of the Conference

'Before concluding, I must say a little about the genesis of this conference.'

'The suggestion originated with Major Hamilton whose work on the eye-fly is the outstanding piece of research carried out in the tea districts during the last few years, in his presidential address at the annual general meeting of the British Medical Association in 1939.

'His suggestion was that the Inspector-General of Civil Hospitals should organize this Conference. The subject was again brought up at last year's annual meeting and Colonel Phipson, whilst strongly in favour of such a conference, thought that it would be better if it were organized unofficially; he promised it his official blessing.

'The obvious organization to initiate such a conference was the British Medical Association, and the Council on behalf of the Assam and North Bengal Branch of the British Medical Association undertook this initiation, agreed to bear the expenses connected with it, and to allow their honorary secretary, who very kindly volunteered, to undertake the secretaryship of the first conference.'

'This conference therefore, though initiated by the Assam and North Bengal Branch of the British Medical Association, is in no sense a conference of that body, but any one doing research work in the province, or on any subject that is of vital interest to the province, was welcome to read a paper at the conference, and attend and join in the discussions. A circular announcing the conference was sent to the Inspector-General of Civil Hospitals, Assam; Director of Public Health, Assam; the Assam Medical Research Society, Dr. Ramsay for the Ross Institute, the medical officers in charge of the laboratories at Cinnamara, Labac, Juri Valley and Nazira; the chief medical officer, Assam Bengal Railway, Dr. Hydricks for the Rockefeller Foundation, Dr. Muirhead Thomson at Tocklai for the London School of Tropical Medicine, and to myself for the Calcutta School of Tropical Medicine.'

CINCHONA CULTIVATION AND THE MUSTARD OIL PROBLEM IN ASSAM

A QUESTION of great importance, not merely to Assam but to India as a whole, was discussed in the Assam Legislative Assembly on Tuesday, the 18th March last, when Mr. Baidyanath Mookerjee moved a cut motion in the House under the demand for grants for forests to criticize Government for not adopting necessary steps for cultivation of cinchona in the province.

It is understood that Mr. Wilson, the expert on cinchona cultivation, who visited Assam also, had expressed the opinion that many areas in Assam were suitable for cinchona cultivation. This shows that if this cultivation had been taken up not only that Assam would not have to import cinchona products from outside the province but probably Assam could supply this commodity to other parts of India.

Mr. Baidyanath Mookerjee in moving his motion said that on many occasions they had raised this point and Government gave their customary reply that 'this matter was receiving their serious attention'. He pointed out that the Hon'ble Premier gave such a reply last year during the budget session when

Mr. Nirendra Chandra Dev raised this question, but this year nothing has been provided in the budget for cinchona cultivation. Bengal Government, he pointed out, had tried this near about Darjeeling and they found it quite profitable, but Assam Government was still waiting. He was told that though Assam Government's experiment at Nongpoli had proved successful, yet it was still in the experimental stage and nothing had been done to increase the area and thereby to save money of the province and to increase the resources of the province. On the other hand Government had budgeted for 15,000 lb. of quinine from Java through the India Government, over and above their usual requirement of quinine.

Dr. C. G. Terrell, who was sworn-in only the day before, made an admirable maiden speech stressing the importance of this drug in the treatment of malaria and requesting the Government to support the project for an increase in cinchona cultivation in the province. He said:—'I am well aware that the price control of quinine is not primarily the concern of the Assam Government, but I would like to suggest that our moral obligations to the community make it most desirable that its influence should be exercised with the Central Government in this matter.'

'Over the pre-war price of quinine there has been an increase of 68 per cent in India Government quinine and 48 per cent in the price of the Java product.'

'I am unable to offer any explanation for the discrepancy which exists in these figures and why India Government quinine should have increased in price so much more out of proportion than that of Java. It would appear that this increase is unjustifiable.'

'The result however must be that the price of this essential drug is beyond the means of the poorer sections of the community and that it has added an additional financial burden to hospitals and industry.'

Minister's reply.—Mr. Rupnath Brahma, Minister, Forests, Assam, in replying to the motion said:—'Mr. Wilson who is an expert on cinchona cultivation had toured throughout India and he came to this province also to make an enquiry and see whether there are lands available and suitable for cinchona cultivation in this province. He submitted a report on the subject in which he recommended some of the areas here in our province. That report had been very lately referred to our Forest Department and unfortunately for that delay we could not include in the present budget any regular scheme for this cultivation. However, I am glad to inform the Hon'ble Members that the areas have been selected in the Khasi and Jaintia Hills according to the recommendation made by Mr. Wilson. Really this will be a great step in the plantation programme. We have placed orders for seeds and I think those will be sufficient to plant up in some of the areas which we have selected. I am glad to inform the Hon'ble Members that in the Khasi and Jaintia Hills at least we are going to have some more cultivation from the next year. I also hope to bring a regular scheme before this House next year. I hope with this the Hon'ble Member will see his way to withdraw the motion.'

On the above assurance the motion was withdrawn by the mover.

Supporting another cut motion Dr. Terrell drew attention to the defects of the Assam Pure Food Act, and the difficulties that existed in the application of its provisions.

He said 'A very important example of this is evidenced by the mustard oil problem. Research work in this connection—with which I had the privilege of being associated at its commencement—has been in progress in this province and elsewhere for more than six years. The findings have all been recorded by workers at the All-India Institute of Hygiene and at the School of Tropical Medicine in Calcutta in the *Indian Journal of Medical Research* and *Indian Medical Gazette*.

These investigations go to prove beyond doubt that mustard oil is frequently contaminated by more-or-less harmful adulterants, and that one in particular, namely

Argemone mexicana, is primarily responsible for the disease known as epidemic dropsy.

Unless it assumes epidemic form this serious disease—with its crippling and sometimes fatal sequelæ—is often difficult to detect. I am however of opinion that in a less acute and more chronic form it is very common, and apart from epidemics, is the probable cause of a serious amount of ill-health and disability.

Argemone contamination of mustard oil is more the result of careless cultivation than wilful adulteration, for the reason that the plant grows freely with the unweeded mustard crops—with which it is cut and gathered, and the seeds closely resemble those of the black mustard variety.

The results to the unfortunate consumer are nevertheless the same, and if, for a brief moment, our minds can attempt to visualize the enormous quantity of mustard oil—frequently contaminated—that is consumed daily by all classes of the community the danger will become apparent to all.

In the light of our present knowledge I venture to suggest—Sir—that the time has come for the introduction of amended legislation to prevent the sale of Argemone-contaminated mustard oil, so as to reduce epidemic dropsy from the status of a major public health problem to that of an interesting pathological curiosity.

It is my belief that this is impossible of achievement by the Assam Pure Food Act, with its many working imperfections; on those occasions when contaminated samples of this oil are located the average individual shrinks from the irksome and unsatisfactory processes laid down for bringing the matter to the notice of the authorities, and even when this is done the results are usually not deterrent to the unscrupulous vendor.

The best methods for achieving a solution of this problem by legislation could far better be propounded by those more experienced and competent to do so than myself.

In certain countries these difficulties have been overcome by Noxious Weed Acts and similar measures, which ensure a crop free from the trespass of dangerous plants and weeds.

I further venture to suggest, Sir, for possible consideration that the mustard oil industry in this province should be directly under the control of Government and the oil sold under licence as in the case of country spirit.

The additional source of revenue to Government could compensate them for the necessary expenditure and place the cultivation, manufacture and sale of this very important commodity on a wholesome and hygienic basis.

They would then have the satisfaction of real achievement and the community would feel assured that when making their purchases whether large or small they could do so without the present fear that it is probably of inferior quality, contaminated with dangerous adulterants injurious to their health. I must apologize for having possibly taken up too much of the valuable time of the House, but it is certain that proper, thoughtful and efficient legislation on this subject would be of lasting benefit to the health and welfare of all in this province.

ARGEMONE MEXICANA

At the annual meeting of the Assam branch British Medical Association, held in Shillong towards the end of March, Dr. C. G. Terrell addressed the meeting on the subject of this plant.

He informed them that certain matters of importance had come to his notice as the result of information passed on to him by Lieutenant-Colonel W. D. Ritchie, I.M.S. (retd.), relating to botanical features of the development of this plant in Upper Assam.

The mustard plant, *rai* or *maghi*, in Upper Assam ripens in the month of January at a time when the

argemone plant is not yet mature. The argemone plant ripens and its seeds reach full maturity at least two months later—in March and April.

The mustard crop is therefore harvested and off the ground long before the noxious weed matures.

This would appear to present—for the first time—a satisfactory explanation of the fact that epidemic dropsy is comparatively very rare in Upper Assam and also by inference provides further valuable evidence in support of argemone contamination of mustard oil as the cause of epidemic dropsy.

In the Surma Valley and Bengal, besides the *rai* there is a slower-growing, taller and stronger plant called *shorsha* which matures later and approximates to the time of ripening of the argemone plant. This crop (of rape) is cut by sickle and not uprooted by hand, as in the case of the short mustard grown in Upper Assam.

From this it is easy to visualize how the seeds of the two plants—which ripen simultaneously and whose seeds much resemble each other—can become mixed when threshed together.

MANUFACTURE OF DRUGS

INCREASING USE OF INDIGENOUS RESOURCES

BORIC ACID for the Medical Stores Department, hitherto obtained from England, may shortly be manufactured in India. It is proposed to purchase crude borax, imported from Tibet, and arrange for the manufacture of boric acid. Another imported article, tablets of magnesium sulphate, 40 grains, is being manufactured by one of the Medical Stores Depots.

Peptone powder, used as a culture medium, has hitherto been obtained from England. It is now manufactured in India. A sample has been tested by the military laboratories and found to be a suitable substitute for the imported article. Accordingly it has been transferred to the list of indigenous articles.

Arrangements are being made for the manufacture of arsenii tri-iodidum in the country.

DRIED ONIONS

With the substitution of dried chipped potatoes in the soldier's ration, further research has revealed the possibility of using dried onions in lieu of fresh ones.

As about 12 maunds of fresh onions yield about one maund of dried onions, there will be a saving in transit and storage. It is claimed at the same time that dried onions keep a long time and do not become rotten so quickly as fresh ones. They take considerably less time to fry and can be boiled in two or three minutes. As they are already cut and prepared ready for cooking, they will reduce the time required for the preparation of dishes.

INDIAN MEDICAL COUNCIL

In exercise of the power conferred by clause (a) of sub-section (1) of section 3 of the Indian Medical Council Act, 1933 (XXVII of 1933), the Central Government is pleased to nominate Colonel H. Stott, O.B.E., M.D. (Lond.), F.R.C.P. (Lond.), D.P.H. (Eng.), K.H.S., I.M.S., Surgeon-General with the Government of Madras, to be a member of the Medical Council of India, from Madras, with effect from the 17th March, 1941, vice Major-General N. M. Wilson, I.M.S., resigned.

In exercise of the power conferred by clause (a) of sub-section (1) of section 3 of the Indian Medical Council Act, 1933 (XXVII of 1933), the Central Government is pleased to nominate Lieut.-Colonel S. L. Mitra, B.Sc., M.B., Ch.B. (Edin.), D.T.M. & H. (Edin.), D.P.H. (Edin.) and (Glas.), I.M.S., Officiating Inspector-General of Civil Hospitals, Bihar, to be a member of the Medical Council of India, from Bihar, with effect from the forenoon of the 21st March, 1941, vice Colonel H. Stott, I.M.S., resigned.

Current Topics

Acute Appendicitis in Children: A Clinical Study of more than 1,000 Cases

By E. M. MILLER, M.D.

E. H. FELL, M.D.

C. BROCK, M.D.

and

M. C. TODD, M.D.

(From the *Journal of the American Medical Association*, Vol. CXV, 12th October, 1940, p. 1239)

THERE is probably no one subject in the entire field of surgery that has aroused more widespread interest among the public and the members of the medical profession than that of acute appendicitis and its complications. Yet the very fact that at this session the American Medical Association is devoting a symposium to this topic, even though more than half a century has elapsed since the pioneer work of Reginald Fitz, seems proof enough that there remains a good deal of uncertainty, at times, as to methods of management of the patient with appendicitis. Much progress, nevertheless, has been made and is being made, especially as the result of careful clinical studies in large series of cases. Too often, however, papers have been written on evidence obtained by a review of hospital records rather than from personal observation of patients, and therefore the conclusions drawn have sometimes not been as reliable as they should be. Too often, also, statistics have been published as to the effectiveness of treatment without clear differentiation between perforations of the appendix which clinically have remained localized (with a definitely palpable mass) and those which have obviously involved the open peritoneal cavity.

We submit here the result of what we consider a careful personal clinical study of well over 1,000 cases of acute appendicitis and its most frequent complications observed by us at the children's surgical ward of the Cook County Hospital, Chicago, during a little more than four years, hoping that from it certain conclusions may be drawn which will be helpful in clarifying the still existing uncertainty as to reliable indications for and against operative intervention.

CLASSIFICATION AND TREATMENT

During the past twenty-odd years of surgical practice it has gradually become apparent to us that, from a clinical point of view, patients with acute appendicitis and its most common complications, whether children or adults, fall naturally into one of three fairly clear-cut, fairly well-defined groups, and we feel that it is highly important for one to decide, or at least to attempt to decide, into which of these each patient belongs, as this decision may materially influence the course of treatment.

Group 1.—This group comprises all patients who are obviously suffering from an attack of acute appendicitis before the stage of perforation. It seems hardly necessary here to elaborate in detail either on the usual 'textbook' picture or on the difficulties that may arise in making a diagnosis when the atypical case is encountered. Suffice it to say (for the purpose of this discussion) that we believe it to be the consensus to-day that appendectomy as soon as the diagnosis is made is the treatment of choice, except for those patients in whom the attack is definitely subsiding. In our study there were 629 patients in this group, all of whom were successfully operated on without a single death. Would that every patient when first seen by the surgeon could be included in this group.

Group 2.—In this group a longer duration of symptoms is noted. The characteristic clinical observations are obviously those associated with a perforation of the

appendix against which there has been set up from the time of perforation an adequate local defensive mechanism. A careful history will usually show that the patient has been sick for several days, perhaps a week or ten days or even longer. He does not as a rule appear desperately ill. The fever may be fairly high and the leucocyte reaction well marked, but he does not have an anxious expression, nor is he suffering intense pain. On abdominal examination with the patient relaxed and the thighs held in flexion, one can make out by palpation the margins of a definite mass, varying in size from that of a walnut to that of an orange or perhaps even a small grapefruit and varying considerably also in position. Though it usually occupies the right lower quadrant, it may be felt well into the right flank; sometimes it is in the left lower quadrant, and not infrequently it is deep in the pelvis, where it can be made out only with the finger in the rectum. Occasionally it is so deeply situated in the main abdominal cavity and so covered by large tense abdominal muscles that its presence is made certain only after complete relaxation induced by an anaesthetic, and in extremely rare instances it may not be discovered until after the incision has actually been made and the walled-off process seen with the naked eye or felt with the examining finger. The point we wish to make is this: Whatever its size, whatever its position and however its presence may be detected, it represents pathologically a slow leak from the appendix, which has become effectively sealed off from contact with the open peritoneal cavity.

As to the treatment of the patient in this group, we are well aware that there is still a considerable difference of opinion even among competent surgeons. Many feel that the majority, if not all, of these so-called appendical abscesses should be drained early, and some even go so far as to advocate a serious attempt at removal of the appendix at the same time. With this attitude we cannot agree; such a policy is neither safe nor necessary. It is not safe, because, if between the wall of that palpable mass and the parietal peritoneum there are normal loops of bowel, spreading peritonitis is apt to be produced by the attempt at drainage; it is not necessary, because in the vast majority of cases the mass will spontaneously disappear. Our study furnishes ample evidence to prove that with more than 90 per cent of these patients careful observation over a period of days will reveal a gradual improvement in the clinical picture, a gradual reduction in the temperature and the leucocyte count, a progressive diminution in the size of the inflammatory mass and, finally, after perhaps ten days to four or five weeks, its complete disappearance, as far as one can tell by physical examination. We advise these patients to return to the hospital after approximately three months, when they are feeling perfectly well. The appendix may then safely be removed, no matter how densely it may have been involved in adhesions. Only a few cases in this group (in our experience) will take the opposite course, with a progressive aggravation of the clinical picture and a progressive enlargement of the palpable mass to the stage at which it represents unquestionably a real 'abscess'. Under these circumstances it will have definitely tried to point somewhere, either anteriorly against the parietal peritoneum, where it can easily and safely be drained through what amounts to an extraperitoneal approach, or downward more deeply into the true pelvis, where it can be felt as a soft bulging mass against the anterior wall of the rectum and where it has a fair opportunity to break through spontaneously without the aid of surgical intervention. In our study, 228 patients have been classed in this group. Of these, twenty-five were operated on for drainage, but I am sure that for some of these the procedure was not necessary, and a longer period of observation would doubtless have shown this to be true. All of the others (203) were given the benefit of watchful conservatism, and of these 198 recovered, a mortality of only 2.5 per cent.

Group 3.—In contradistinction to those in groups 1 and 2 the cases included in group 3 represent acute perforations of the appendix into the open peritoneal

cavity; perforations against which there has at no time been established an adequate defence. Pathologically speaking, in many of them the condition is of the obstructive type, with a large faecal stone, and the perforation is grossly of considerable size. To use a crude simile, it is not unlike a sudden 'blowout' of a tire, in contrast to a slow leak. Often the streptococcus is the predominant organism, and often too the patient's resistance to infection is low. As a rule he looks very sick; there is a pinched, anxious expression; the tongue is dry; the pulse is fast, and the fever and leucocyte count are variable. The knees are held in flexion; the breathing is thoracic; the abdomen is distended; on palpation one finds the muscles everywhere tense, and there is more or less general tenderness, at times even in the left flank. The whole picture is suggestive of spreading peritonitis.

What shall we say as to the care of this patient? Has he a better chance to recover if he is not operated on and use is made of the so-called Ochsner method of treatment, with Fowler's position, adequate physiologic solution of sodium chloride and dextrose given by vein and under the skin, restriction of fluid by mouth, a Levine tube for relief of distension, and administration of mild sedatives, in the hope of diminishing peristalsis and perhaps of localizing the spreading infection? Without question, a number of surgeons hold this view (many of prominence among them), and it would take a bold critic to claim that such measures are not of great value. But we would ask these surgeons: Would they apply this conservative regimen to all patients in this group or to only a few? And if to only a few, to which ones? Would they apply it only in the late stages or in the early ones as well? Would they apply it only to patients with evidence of widespread involvement of the peritoneum or to those also in whom the infection is apparently limited? We have often heard it said that if the patient has been sick for less than forty-eight hours he should be operated on; if for more than forty-eight hours, operation will be withheld. Some place the limit of time at even less; others would arbitrarily fix it at fifty-six hours or even more. To these points of view, we blithely and in all seriousness express our belief that no physician, however wise he may be, can hope to judge accurately the rapidity of pathologic changes; no physician, even from the most carefully obtained history (especially with children) can be certain as to the exact duration of the attacks of appendicitis (which is so often preceded or accompanied by other things which cloud the picture); no physician can always be sure of the exact time when the perforation has occurred, nor can he be certain, even by the most painstaking examination, of the extent of involvement of the peritoneum by the spreading infection. If these statements are true, why should one allow such unreliable criteria as these to influence one as to the decision for or against surgical intervention?

The answer is that one should not. We are of the firm opinion that those who advocate a conservative course with patients in this group are wrong, because it appears to us that the essence of the treatment should consist in removal of the ruptured appendix, which closes the leak through which a constant stream of infected material is being fed into the peritoneal cavity. Just as with an open perforation of a duodenal or a gastric ulcer, the essential thing is to close the opening as soon after it occurs as possible. With us there has been, therefore, an ever increasing tendency over a period of years to apply this policy of immediate operation to practically all patients in this group, no matter how long a time has elapsed since the onset of illness, and we are more and more convinced of the wisdom of this course. We do not, however, wish to give the impression that when we use the term 'immediate operation' we mean that the patient is sent from the admitting room to the operating table, for long since we have seen the value of adequate preparation, with restoration of the electrolyte and fluid balance, relief of distension as far as possible with a Levine tube, and finally, use of a measure which has lately been emphasized by Gatch and his associates

and has been used by us empirically for a long time, i.e., replacement of lost plasma protein (both before and after the perforation) by means of blood transfusion. A brief outline of the operative procedure for patients in this group, perhaps little need be said. The McBurney incision is almost always employed. Cultures are always made of the free pus when the peritoneum is opened. The Poole suction tip has practically replaced the use of sponges in the abdominal cavity. The perforated appendix is delivered with a Babcock forceps, which encircles its wall; the stump is always ligated with catgut and whenever possible is buried beneath a catgut purse string. As to the matter of drainage, there is still considerable difference of opinion among our own group as to its value. Some are bold enough to close these incisions without a drain. (We have had occasion several times to open these incisions later to allow free evacuation of foul-smelling pus, and in one instance, in which a diffuse anaerobic phlegmon of the entire right abdominal wall had developed subsequent to a tight closure, we were obliged to reflect enormous flaps of skin to expose the area involved to the open air.) A few prefer to close the peritoneum and drain only the incision itself. We believe, as do most other surgeons, that it is not mechanically possible completely to drain the infected peritoneal cavity by the introduction of one or more tubes, yet we continue to use drainage in every case of perforation, always employing drains of the soft cigarette type and always placing them as near the source of the infection as possible. Especially do we feel that they are of value when the perforation has occurred behind the cecum, because they may help to prevent an ascending infection in tissues not protected by peritoneum and thus minimize the likelihood of a subphrenic abscess.

With what success has this regimen been rewarded? In this period of a little over four years 306 patients have been classed in group 3. Of these, only twenty-five (8 per cent) were treated conservatively, with a mortality of 80 per cent, whereas 281 (90 per cent) were given the benefit of 'immediate' operation, with 242 recoveries (mortality, 12.8 per cent). It will also be noted that in the past two years all patients were operated on, no matter how much time had followed perforation.

CONCLUSIONS

1. Immediate appendectomy is indicated in all cases of acute appendicitis before perforation unless the attack is clearly subsiding.
2. When the clinical evidence shows that the appendix is ruptured and the infection is definitely localized (demonstrable by a palpable mass), a conservative course is indicated. Only a few patients will need surgical drainage.
3. In all cases in which spreading peritonitis is present without evidence of localization, it is a wise plan to remove the source of the infection as early as possible, institute proper surgical drainage and make every effort postoperatively to restore to the circulating blood whatever elements have been reduced as the result of the infection.

Significance of the Tonsils in the Development of the Child

By A. D. KAISER, M.D.
(Abstracted from the *Journal of the American Medical Association*, Vol. CXV, 5th October, 1940, p. 1151.)

During the last thirty years many significant facts have been ascertained relative to the growth and to the development of the child. Particular attention has been given to the status of the tonsils and adenoids as one of the factors that may influence the child's physical progress. In this period an increasing number of children have been classified as possessing hypertrophied or diseased tonsils resulting in the surgical treatment of the tonsils in nearly 50 per cent of urban

children in the United States and England. This situation invites a survey of the tonsil problem and an evaluation of the tonsils as a factor in the child's development.

The tonsils have assumed an important rôle in the economy of the child during the last thirty years. The beneficial results following tonsillectomy in selected cases inspired this procedure on a large percentage of children often without a good reason.

Follow-up studies on tonsillectomized and non-tonsillectomized children were undertaken to show the trend of certain complaints over a ten-year period in the two groups and to note the effect of the tonsils on the physical development of the child.

It was shown that markedly hypertrophied tonsils and tonsils that are repeatedly inflamed giving rise to attacks of tonsillitis and cervical adenitis frequently do impair normal physical development. When such a condition exists after the age of 4 years it is advisable to have the tonsils removed, with the expectation that at least 50 per cent of the children so treated will be materially improved.

Such infections as the common cold, otitis media, sinusitis and laryngitis may unfavourably influence the child's normal development. It cannot be demonstrated that the tonsils are often a causative factor in these infections; consequently tonsillectomy does not offer a solution for their eradication save in exceptional cases.

It could not be shown that the incidence of such diseases as bronchitis, pneumonia and tuberculosis was reduced in tonsillectomized children. The tonsils are not often responsible for pulmonary infections.

Rheumatic disease and nephritis constitute serious handicaps to a child's normal development. Recent studies show that the tonsils play a less significant rôle in the causation and treatment of these diseases than was formerly supposed. However, a reduction in the number of throat infections following tonsillectomy has a beneficial effect in the rheumatic subject.

There has been a significant decline in the mortality and morbidity rate of children during the last three decades. There has also been an improvement in the physical development of children in America. The application of the new discoveries in the field of nutrition, immunology and sanitation has contributed much to this favourable situation. When proper consideration is given to these factors it is evident that the tonsils are not as great a menace to a child as has been frequently suggested.

There is substantial evidence that in about 20 per cent of the children the tonsils are either hypertrophied or diseased and therefore have an unfavourable influence on the physical development of the child. Such tonsils should be removed.

Chemotherapy of Meningococcal Meningitis

By H. STANLEY BANKS, M.D., D.P.H.

(Abstracted from the *Lancet*, Vol. II,
28th October, 1939, p. 921)

Of a total of 147, the first 65 cases of acute meningococcal meningitis were treated with serum in intensive intravenous dosage and sulphanilamide in somewhat varying dosage. There were 8 deaths, a case-fatality rate of 12.3 per cent for treated cases, 13 complications and 3 known sequelæ (deafness). These figures are exclusive of 6 cases in which treatment could not be applied, and of these 4 were fatal. The gross mortality from the disease during the currency of this series was, therefore, represented by 12 deaths in 71 cases or 16.9 per cent.

Next 72 cases, comparable to a high degree, were treated by chemotherapy alone in high dosage, 31 with sulphanilamide, 36 with M. & B. 693, and 5 with a combination of both drugs. There was 1 death, giving a case-fatality rate of 1.4 per cent for treated cases, 6 complications and 2 known sequelæ (deafness). Four cases, untreated or inadequately treated, and all fatal, were excluded from this series. The gross mortality from the disease during the currency of this

series amounted, therefore, to 5 deaths in 76 cases, or 6.6 per cent.

Initial dosage of sulphanilamide sufficient to maintain a c.s.f. concentration of 5 mg. per cent for three days and a lesser concentration for a further period of five or six days is the minimum reliable standard. Low initial dosage is distinctly unsafe.

Intensive intravenous serum therapy does not compensate for low dosage of sulphanilamide. No evidence in favour of auxiliary treatment with serum was obtained.

Similar high dosage is recommended for M. & B. 693, although there is evidence that lower dosage of this drug will often be successful.

Persons of all ages were amenable to chemotherapy. Infancy is not now an age of unfavourable prognosis, but further experience is required for prognosis in the age group over forty.

Groups I and II meningococci are equally susceptible to chemotherapy.

The oral route can be used throughout in most cases. For vomiting or difficulty in swallowing, an occasional intramuscular injection of M. & B. 693 soluble (sodium solution) is convenient.

In certain cases a combination of M. & B. 693 and sulphanilamide is serviceable.

Testosterone Propionate in Chronic Mastitis

By A. W. SPENCE, M.B., F.R.C.P.

(Abstracted from the *Lancet*, Vol. II,
14th October, 1939, p. 820)

THE cause of chronic mastitis is doubtful, but laboratory evidence suggests that the changes in the breasts may be due to the action of ovarian hormones, more especially oestrogens. Ovarian activity is inhibited by suitable doses of male hormone, and Desmarest and Captain were the first to report favourable results in chronic mastitis by intramuscular injections of testosterone acetate. In 16 of 17 patients it brought about relief of mammary pain and diminution or disappearance of adenomatous nodules. Turpault and Bender have recommended testosterone propionate for the treatment of mastodynia, and Loeser, using larger doses, observed the disappearance of nodules in 3 patients treated. In the present series of 24 patients with painful breasts and/or so-called chronic mastitis, 16 were treated with testosterone propionate with dramatic relief of pain in most cases; diminution of the nodules, although effected in some patients, was less striking.

Of 24 patients with painful breasts and chronic mastitis treated with intramuscular injections of sterile olive oil (as a control), pain was relieved in 13, whether they had lumps in the breast or not. No further treatment was given to 8 of these 13 who had no lumps.

The remaining 16 patients were treated with testosterone propionate injected intramuscularly in doses of 25 mg., 50 mg., and 100 mg., usually twice a week for several months. In 14 patients pain was relieved.

In 12 patients treated there were lumps in the breast; in 3 the lumps disappeared, but in 2 of these spontaneous disappearance could not be excluded, and in 1 2,925 mg. in five months was required, resulting in hypertrophy of the clitoris and extreme atrophy of the endometrium. In 5 patients there was some reduction in the size of the nodules. In 2 patients who were not improved fresh nodules appeared in the breast during treatment.

Menstruation was suppressed in 7 patients receiving the larger doses.

Increased growth of hair developed in 5 of the younger patients, in 4 with comparatively small doses, but this was not observed in older patients receiving much larger doses. It is emphasized that because of this complication and the undesirability of prolonged atrophy of the endometrium, testosterone propionate should be used with caution in women.

Prevention and Treatment of Decubitus in Fractures

By T. A. FOX, M.D.
and

G. L. APFELBACH, M.D.

(Abstracted from the *Journal of the American Medical Association*, Vol. CXV, 26th October, 1940, p. 1438)

DECUBITUS is a major problem of a fracture service having an annual turnover of 1,400 patients. In spite of prophylaxis, its incidence is such that it frequently overshadows the original surgical condition requiring hospitalization. Bedsores often prevent open reduction.

The foreign and American literature offer little truly investigative work regarding aetiology or prophylaxis. We here report a newly developed technique in the prophylaxis and treatment of decubitus.

A series of 232 cases were followed over a period of three months. The average age was 51 years. There were seventeen patients with fractured hips, from 60 to 95 years old, ten who were diabetic, six with fractured pelvis, and one who had a compression fracture with paraplegia. Of the original fifty-five patients six had simple decubitus while twenty had deeply necrotic bedsores.

Pressure is recognized as the chief cause of decubitus. It occurs usually over the sacrum, buttocks and heels, and less commonly over the malleoli, greater trochanters, scapulas and elbows. Pressure also occurs at the upper and lower edges of casts and at the ring of a Thomas splint. Trauma may be a contributing factor, caused by friction from bedclothes, rucks in sheets or dressings, gritty dusting powder or plaster, bedpans or other features of nursing care. Moisture, as in perspiration, urine or faeces, macerates the skin and allows the entrance of infection. Senility, with its associated atrophy of the skin, is also a predisposing factor. Pressure areas due to lack of muscular development are more common in women. The skin of the Negro is less susceptible to decubitus. Hypovitaminosis is likewise a predisposing factor. Anorexia, poor dentures and associated dietary deficiency are common in the aged. The malnutrition and hypovitaminosis of alcoholic patients are well recognized. Hypoproteinæmia with oedematous skin, dehydration and chronic shock are frequently associated factors. Incontinence of urine or faeces is commonly encountered, especially in the aged, and cord injuries lead to trophic disturbances with resulting infection. An increased incidence of bedsores in disease of the pancreas is recorded.

Love classifies bedsores as follows: stage 1 (threatened), with generalized redness of the skin which blanches readily and immediately reappears when the pressure is released; stage 2 (inevitable), with increased redness which assumes a purple hue, pressure causing no blanching. Early a vesication occurs over the purple-red area. These small vesicles and blebs soon break, close scrutiny being required to discover them. The resulting weeping surface is ideal for infection. The stage passes into stage 3 (ulceration), with sepsis and toxic absorption.

We observed that these pressure areas resemble the blebs and vesicles of a second degree burn. Latimer also records this fact. In burns the skin is injured by thermal trauma with local oedema and bleb formation. Decubitus pressure, from body-weight or cast, causes dilatation of subcutaneous vessels and increased irritability of vasomotor endings in the skin; this results in the initial erythema with ready blanching on pressure. With continued pressure there is vasomotor paralysis and stasis. This accounts for the purple colour and failure of the tissues to blanch on pressure, which in turn produces local oedema and bleb formation.

Decubitus causes little pain, at least after the first day, probably owing to a pressure palsy of sensory fibres and to oedema of the skin. With proper treatment only the first two stages should occur. Lesions in our cases never reached the stage of ulceration.

In the treatment of decubitus, prophylaxis is of the utmost importance. The breaking down of the skin must be avoided. With this in mind a 'calamine varnish',* a mechanical and pharmaceutical aid, was developed. All pressure points are washed with tincture of green soap, alcohol and ether. The calamine varnish is applied with a brush and allowed to dry. Ordinary photographer's rubber cement is then spread over the same area and allowed to dry. These form a thick elastic coat over the points of pressure. The soothing astringent antiseptic coat, with its protecting layer of rubber, forms a pressure-proof, bacteria-proof, moisture-proof prophylaxis for decubitus. This is a routine procedure in the fracture ward. It may be repeated as often as necessary. It prevents the breakdown of tissue.

Careful observation of the patient's skin is essential. Should vesicles or macerations appear they are immediately debrided and sprayed with a 10 per cent solution of tannic acid and 1 per cent salicylic acid. When dry a 10 per cent solution of silver nitrate is painted over the area. This forms a black supple thin tough crust which gives a 'new skin' surface and requires no further treatment. With infection and necrosis, fresh diluted solution of sodium hypochlorite is used freely. We do not cauterize exuberant granulations. This only adds a necrotic crust to a clean surface. A razor trims the overgrowth of tissue to the level of the skin surface. Epithelium can then bridge the gap.

Since recovery in the twenty original cases, there have been no deep ulcerations. When clean they are treated as described. Skin grafts may be necessary. There was only one instance in our series. Latimer describes the use of tannic acid in the treatment of necrotic decubitus and this method has been used by Love, Spiesman, Cope and many others. Nayrac and Morel described the use of 5 per cent silver nitrate to stiffen the skin in early lesions. Proper application of prophylaxis, as outlined, should in most instances prevent decubitus with fractures and chronic illness. With the simple treatment here outlined the existing bedsores readily heals. The prognosis of decubitus is improved. Patients requiring surgical therapy need not forego its benefits because of bedsores.

Closed Plaster Treatment of Infected Wounds

By G. R. GIRDLESTONE, F.R.C.S.

(Abstracted from the *Lancet*, Vol. II, 13th July, 1940, p. 31)

THE 'closed plaster method' has been assembled part by part; and it is well to consider separately each process with its purpose, for there is no need to reject enclosure of the wound and immobilization of the soft tissues because the full ritual is unnecessary or in part contra-indicated.

1. The débridement; the general rule is to excise, as far as practicable, infected tissues, and tissues devitalized by bruising or by the impairment of circulation. This rule governs the excision of skin, connective tissue and muscle; surgical sense will guide the operator when he reaches more delicate ground.

2. To lay open rather than suture when suturing would involve tension and devitalization of the skin or deep parts.

3. A varying degree of 'saucerization', which allows natural retraction of the muscles to the position of equilibrium, and involves a laying open for the free drainage of all pockets or areas of heavily infected or

*Tragacanth 2 per cent, benzoic acid 1 per cent in Ringer's solution to make 100 per cent. Add to this prepared calamine N. F. 7.5 per cent and bentonite 2.5 per cent. The calamine and tragacanth are well known emollients. The bentonite is a mildly antiseptic astringent aluminum silicate clay and the benzoic acid a preservative.

damaged tissue which cannot properly be excised. For serious destructive wounds the requirements vary from the saucer to the cup; but there are many wounds, earlier and less destructive, in which no such formal exposure of the deep tissues is indicated. At times nothing more may be needed than a single layer of broad wick laid between the edges of the wound after débridement.

4. The plaster splintage with its dual purpose: (a) the restoration of function, by keeping the bones, joints and muscles at rest in the chosen position; (b) defence against the spread of infection, by keeping the reactionary cellular infiltration undisturbed in the tissues and lymph-channels round the wound.

5. A particular technique of enclosure of the wound in that part of the plaster which covers the exposed tissues. It should apply an even gentle pressure similar to that normally exercised by the fasciae and the skin.

6. The elimination of frequent dressings, which mean either pain or repeated anaesthesia for the patient and are both time-consuming and expensive.

Trueta lays stress on (a) the good vascularity of the tissues left after débridement; (b) the avoidance of any traumæ or antiseptic application to these tissues; (c) the avoidance of tight packing of the wound, or other firm pressure on exposed tissues; and (d) the application of gentle uniform pressure over a thin and evenly applied gauze dressing. He approves of a single layer of vasclined fine-mesh bandage under the gauze to prevent granulations growing into the loose meshwork of the gauze.

The success of the closed plaster method depends on its correct application to the individual case, on the judgment and skill displayed in the earlier processes and on the perfection of the plaster work. It is desirable to keep the patient under supervision for two or three days, for only thus can one be sure that the plaster is comfortable and that no untoward signs are developing. Hasty evacuation may make this impossible, but if the treatment has been efficiently carried out the patient should travel in safety and comfort.

SOME FALLACIES

It has been said that after a certain period, say, two or three days, the closed-plaster method is not applicable to a dirty wound because excision of the wound is no longer practicable. This is a great mistake. In my opinion no method of treating such a case can compare with closed plaster after sauerization, which may include laying open all heavily infected areas. A wound that will benefit from sauerization and enclosure does not always need excision; indeed, excision is generally contra-indicated in the presence of established sepsis. On the other hand a late wound which has been unsuccessfully treated by excision and suture may need the whole ritual, as in the case here described, where there was necrosis of the sutured skin, widespread and deep-seated infection and devitalized deep tissues.

Again, it has been said that for wounds near a joint this method is unsatisfactory on account of resultant stiffness of the joint. It is true that when early excision and suture without tension can be undertaken the method need not be applied. But where the wound has involved the widespread laceration and devitalization of tissues, or where, due to lapse of time, there is spreading infection, the closed plaster method, when compared with an attempt to achieve closure by imperfect excision or by strong tension suture, gives not only relative safety of life and limb but also a better prospect of movement. In all extensive wounds near joints the posture of the limb with reference to the situation of the wound is of great importance. It is usually possible to foresee which movements are likely to be restricted by cicatrization, and to put up the limb in a position which will favour the difficult movement.

The method has been decried because a number of wounded men treated by closed plaster in France and Belgium have reached hospital in this country with wounds doing badly or miserably from extensive pressure-sores. Probably the surgeons were imperfectly

familiar with the method, certainly their plaster-work failed to stand the severe test of early evacuation and a very long journey.

PLASTER-OF-PARIS IN WAR-TIME

He who would apply plaster in war must be skilful in its use, or he will be a danger to his patients and bring undue discredit on the method; he had far better continue to treat wounds on more familiar lines. It is unfortunate that the most helpful plasters are the most exigent. It is difficult enough in favourable circumstances to put on, under anaesthesia, the plaster required for an extensive bomb wound involving a shattered humeral shaft. Such a plaster includes the whole upper limb with the trunk and pelvis; for the 'plaster of splintage' must obtain a complete and comfortable hold upon both proximal and distal parts if the 'enclosure plaster' is to exert an even and unvarying pressure all over the wound and its neighbourhood. Wherever considerable weight is to be carried on the plaster, as in a shoulder or a spica plaster, protection of the areas of pressure by padding is desirable, preferably by soft white felt.

If this closed plaster method is to give results as good as those for bomb wounds in Barcelona or gunshot wounds in Madrid those who use it must fully understand each process. Unfortunately plaster technique receives little attention in our medical schools. Few students or house-officers have the opportunities of learning how to apply extensive plasters which will accurately and comfortably control the whole trunk and one limb. If a wound is to do well it must first be given appropriate operative treatment; after this the progress of the wound and the comfort of the patient depend on the fit and inner smoothness of the plaster.

The surgeons of the last war found themselves abandoning antiseptics in favour of débridement, packing and less frequent dressings; later Winnett Orr enclosed the wound; to Trueta we owe the finer developments of the technique and its adaptation to varying degrees of destruction and infection in the light of his unique experience and scientific study.

Pharmacological and Therapeutic Action of "Calci-Aurum" (a gold preparation of Ancient Hindu Medicine)

A Monograph from the University Hospital, Hamburg

By D. DWĀRAKĀNATH, M.M.

and

HERBERT SCHÖLZ, Dr. phil.

THERE is an old Indian gold preparation which was known in Ayurveda and was prepared in India. After quantitative analysis, solubility experiments were carried out whereby it was proved that the preparation possesses an oligodynamic action and can be partially dissolved by the juices of the body.

In animal experiments it was shown that by oral administration, gold is absorbed from this drug and is excreted from the circulation through the kidneys.

The preparation does not show any toxicity.

In normal animals (guinea-pigs) the gold is stored in the cells of the reticulo-endothelial system. This fact was also demonstrated by photomicrography.

In animal experiments, an increased appetite and an improvement in general health were observed after the preparation was given for only a short time. After feeding with the gold compound for four weeks there was a significant increase in weight in all the experimental animals.

In animals injected with diphtheria, an increased resistance against inflammatory processes (infectious) was demonstrated. The animals treated with the gold

preparation resisted the toxin poisoning longer and with effective resistance.

A new method for the identification of the minutest quantity of gold in organic and inorganic substances was worked out and used.

The gold is also absorbed by human beings and it is stored in the reticulo-endothelial cells.

Increased appetite, betterment of general health, diminution of temperature and a good increase of

weight as a result of these manifestations have also been observed in tuberculous patients.

The administration of this preparation is also recommended in those cases in which a solgona treatment is contra-indicated.

The last three effects were observed in patients whose condition had so far advanced that a cure was thought out of the question. In better cases, clinical and x-ray evidences proved the improvement and stoppage of the processes.

Reviews

SURGERY OF THE MODERN WARFARE.—Edited by Hamilton Bailey, F.R.C.S. Compiled by 65 contributions. Part I. Section I.—Wounds: General considerations. Section II.—Wounds: Special considerations. 1940. E. and S. Livingstone, Edinburgh. Pp. iv plus 160. Illustrated. Price, 12s. 6d. Postage, 6d.

Our knowledge on traumatic surgery at the beginning of the last war was very different from our knowledge on this subject at the end of that war; still further changes had occurred by the beginning of the present war; to-day we know much more than we did in September 1939; and one may reasonably assume that by the end of this war considerable further changes will have taken place. Therefore, the best time to write a book on war surgery would, from a theoretical point of view, be at the end of this war; the book would, however, by then, we all hope, be almost useless. After a little over a year of war, during which period theories born in peace time (and in other people's wars) have been tested and procedures modified, a point has been reached at which there is a considerable degree of stability in war-surgery practice; this seems to be the psychological moment for the publication of an authoritative book on war surgery.

The decision to publish this book in parts was also a very wise one, as it obviates the inevitable delay associated with the publication of a large volume. When the last part has been published the publishers have promised that a suitable binding will be issued.

Should one entertain any doubts as to the authoritative nature of the publication, it is only necessary to read the list of contributors to dispel these, for the list contains the names of many of Great Britain's leading surgeons, all of whom are unfortunately in the front line in this war on civilians.

If the whole publication can be judged on part I, it will be a remarkably practical one. After two introductory chapters on instruments of destruction and the classification of war wounds, the editor puts first things first and gives us a chapter on shock, appropriately followed by one on transfusion. The latter constitutes the best account of the technique of this invaluable life-saving procedure that the reviewer has had the pleasure of reading. There are only 27 pages devoted to the subject, but every step of the procedure, from the blood grouping onwards, is given in minute detail, and usually illustrated. Still maintaining the natural sequence, the next chapter is on anaesthesia. Chapters on war burns, the localization of foreign bodies, the local treatment of recent wounds and of infected wounds follow, and the section concludes with a useful chapter on chemotherapy. Section II, which is also included in part I, contains eight chapters, still on general subjects such as gas gangrene, tetanus, suturing, and skin grafting.

The book is profusely illustrated; many of the illustrations are in colour. It is a matter of wonderment to us in this country that medical books, in fact books of all kinds, still seem to be produced in Great Britain, and that, up to date, there is not the slightest sign of deterioration in quality. This book is a particularly good example. No surgeon can afford to be without this book, for, even if he is not in the

front line to-day and does not propose to volunteer to-morrow the front line may move to his door.

(Parts II and III have been received and will be reviewed in a subsequent number.)

EDINBURGH POST-GRADUATE LECTURES IN MEDICINE. Volume I. 1938-1939. Published for the Honyman Gillespie Trust. By Oliver and Boyd, Edinburgh. Pp. xvi plus 513. Illustrated. Price, 10s. 6d.

THERE are in this volume thirty-three lectures on a diversity of subjects, all of which have a direct or an indirect bearing on medical practice; the lecturers include specialists in almost all branches of medical science, for the most part associated with the Edinburgh medical school.

The lectures are nearly all of an eminently practical nature and the doctor who could not get away from his practice to attend the post-graduate course, or courses, where the lectures were delivered, will gain some compensation by having this opportunity of reading them in a concise form, and being able to refer back to them when he has forgotten a point.

Medical readers will appreciate this volume whether they were educated in Edinburgh or not, but for the latter there will be a particular appeal.

Professor Davidson's article on macrocytic anaemias will be read with very great interest in India, and his classification will be very helpful. All the types that he includes are represented here, but we believe that there are others. Professor Goodall, in his lecture on pernicious anaemia, emphasizes a very important point which has its application far beyond the subject of his lecture; this is his appeal against polytherapy in anaemia:—

'I would plead for the avoidance of speculative therapeutics by the use of preparations of liver with iron. Any need for the combined use of liver and iron is rare, and the indications for such treatment afford difficulties even for an experienced haematologist. The harm done by liver and iron combinations is that treatment by the necessary ingredient is generally half-hearted, while the other ingredient is useless. The half-hearted treatment often leads to a condition of semi-invalidism and the appearance of a blood picture exceedingly difficult to diagnose. If the patient recovers, no one knows what he has recovered from, and maintenance treatment is apt to be either inadequate, or to be given unnecessarily.'

This applies with even greater force to the treatment of fever in India.

In his lectures on occupational therapy, we see the lecturer, Colonel J. Cunningham, in an entirely new rôle. A decade or more ago, he was a frequent contributor to the medical literature in India, on bacteriology and closely allied subjects, but Colonel McKendrick, a contemporary of the former, lectures on a subject that has always been his own, the dynamics of crowd infection.

The reviewer notes with very great pleasure the words 'Volume one' on the title page; this pleasure will, he feels confident, be shared by the reader who follows his advice and purchases a copy of this book.

THE NEW INTERNATIONAL CLINICS.—Edited by George Morris Piersol, M.D. Volume I. New Series Three. 1940. J. B. Lippincott Company, Philadelphia and London. Pp. iv plus 319. Illustrated. Price, 60s. for 4 volumes published quarterly.

This well-known series of practical and important articles on subjects of special interest to the general practitioner still maintains its high standard.

The present volume contains a number of interesting articles of the usual quality. It is difficult to single out one article for special mention, but Drs. Held and Goldblom on 'Jaundice' particularly appealed to the reviewer who is looking forward to the second half of this article that is promised in the next volume.

Another article, on the treatment of prothrombin deficiency with vitamin K by Dr. J. E. Rhoads clears up some confusion that existed in the reviewer's mind regarding the various substances that are labelled 'vitamin K'. This substance seems to have provided one of the few examples of successful gilding of the lily, for the chemist has produced a synthetic substance that is more active than the natural vitamin.

That very difficult problem of the relation of gastritis to anaemia is tackled by Dr. T. G. Miller; he accepts the general opinion that gastritis plays no part in the aetiology of pernicious anaemia, but rather grudgingly, as he finds the two conditions so consistently associated.

'The Review of Recent Progress' with which the volume concludes is on vitamins and it provides, in about eighty pages, a very comprehensive summary of our present knowledge on the important vitamins, A to E and K.

The articles are well worth the permanent form given to them in the well-bound and handy volume of this series.

MODERN MEDICAL THERAPY IN GENERAL PRACTICE.—Edited by David Preswick Barr, A.B., M.D., LL.D. Volume I. General Therapy Methods used in Therapy, General Diseases. 1940. The Williams and Wilkins Company, Baltimore. Volume I—Pp. xlii plus 1200 plus xxx. Illustrated. Obtainable from Messrs. Ballière, Tindall and Cox, London. Price for three volumes—£9-12-6

THIS is not an ordinary dictionary of treatment. In the first place it consists of three large volumes. The first volume deals mainly with the subject in a general way. The book is not divided into numbered chapters or sections, but the subject is dealt with under a number of headings, e.g., psychotherapy, the use of drugs, vaccines and sera, organotherapy, dietotherapy, physiotherapy, etc. This covers over seven hundred pages of the volume; in the remaining four hundred odd, the treatment in specific groups of diseases is given, e.g., allergy, deficiency diseases, diseases due to chemical and physical agents, and intoxications.

There are about a hundred contributors; the large majority of these hold teaching appointments in American universities or medical schools. Each section, and in many cases the sub-sections, are well annotated, and in some instances where rare conditions are being dealt with the writer is content to refer the reader to some other publication; there is much to be said for this procedure, for it saves overloading the text with details which will very rarely be required; individuals may take exception to this, but it will benefit the majority. A good example is bacteriophage; in this 3700-paged work it receives less than a page, but there are eight references. The writer incidentally gives it no place in therapy.

The section of dietotherapy is unfortunately named and to the British reader the word conjures up the semi-quack diet whose initiator makes a fortune by selling his popular book in which he expounds his totally unscientific hypothesis in pseudo-scientific language. This section is not of this nature at all, but is a very valuable and complete discussion on dietary requirements in health, with tables of the constituents of various foodstuffs. There is an entirely separate

section on deficiency diseases and yet another on diseases of metabolism; it is in both these groups of diseases that dietotherapy, as we visualize it, plays a supreme part.

Sprue is classed as a deficiency disease. The condition described is not the disease that we see in India though it has many of its features. The treatment advocated is the American version of Fairley's high-protein diet and would be suitable for a European or American subject with this disease. The section on diseases of metabolism is a large one of about 130 pages, and is virtually a small textbook on diabetes; the treatment of obesity is, however, included in this section.

We have only one criticism to offer, namely that the main section heading appears at the top of the right-hand page and one therefore receives no assistance in finding any particular sub-section.

This work will be found extremely useful in this country; it presents the American point of view, which in the reviewer's opinion is quite often the right one.

The other two volumes have been received and will be reviewed in a subsequent issue.

TREATMENT IN GENERAL PRACTICE: SURGERY (CONTINUED). ARTICLES REPUBLISHED FROM THE 'BRITISH MEDICAL JOURNAL'. Volume IV. 1940. H. K. Lewis and Company, Limited, London. Pp. x plus 562, with 143 illustrations. Price, 16s.

THIS is the fourth volume of this series; we are glad that the war has not prevented the publication in book form of these very useful articles on treatment in general practice. The third volume was on anaesthesia and surgery, and this volume continues the subject of surgery. The volume contains articles mainly on what would be classed as minor surgery, but a few are definitely major, e.g., fractures and dislocations of the spine, and there is rather surprisingly an article on the treatment of ringworm of the foot; this is a useful article, but does not perhaps sufficiently emphasize the dangers of over-treatment of this troublesome condition.

The authors are representative of the best British writers on surgical subjects, the treatment advocated is up to date but usually orthodox, and is in most cases clearly presented. The volume forms a very valuable addition to the series.

DISEASES OF INFANCY AND CHILDHOOD.—By Wilfred Sheldon, M.D. (Lond.), F.R.C.P. (Lond.). Third Edition. 1940. J. and A. Churchill Limited, London. Pp. xii plus 756, with 130 text-figures and 14 plates. Price, 24s.

THIS book has already acquired a reputation as a very sound and practical book on the diseases of children, in its first two editions. The first edition only appeared in 1936, so that it is comparatively a new recruit to the field of pediatrics; its author however is not, and the book has the advantage of his long practical experience in the treatment of children, as well as his obvious ability to present his subject completely and concisely in a manner suitable for the student or practitioner. For the latter, it forms a very valuable book of reference.

The new matter in this edition, naturally, is mainly concerned with the use of the sulphanilamides, but information on other important subjects has been added, e.g., the Vollmer test for tuberculosis; this test does not entail any injection or scratching, and the reaction is produced by contact of tuberculin with the skin only. It will be popular where children (or their guardians) are nervous of the needle, but it is not quite as delicate a test as the well-established Mantoux test.

There are some very valuable appendices, which have been added in this edition. One gives the contents of the various vitamin preparations, proprietary and otherwise. Another is a sulphanilamide dosage table for infants and children.

The book is punctuated profusely with prescriptions; these will prove of great value to practically minded readers, even if they are a source of irritation to the fastidious ones, for the writer has shown a fine disregard for uniformity and Latin case. He has worked an

incredible number of changes by varying his abbreviations and his use of capitals, by alternating Latin and English forms, and quite frequently by mixing them but perhaps the printer is to blame for the period after *ad*. Anyone who has written a book will realize that there is plenty of excuse for lack of uniformity in a first edition, but in a third it indicates either carelessness or calculated disregard for niceties. The book would gain immeasurably in the eyes of the fastidious reader—and let me assure the author and publishers that there are many such—if in the next edition the prescriptions could be written in their full Latin form with the correct cases observed; the work could be relegated to a secretary. From a practical point of view the book would lose nothing.

However, the prescriptions as they stand will have a special appeal to the practitioner in this country, and in fact, though there is little reference to tropical conditions, it is a book that we can strongly recommend to readers of this journal.

HYPERTENSION AND NEPHRITIS.—By Arthur M. Fishberg, M.D. Fourth Edition. 1939. Ballière, Tindall and Cox, London. Pp. 779. Illustrated with 40 engravings and a coloured plate. Price, 37s. 6d.

THIS famous book, which has entered its fourth edition, needs no introduction. Since the publication of its third edition much work has been done in the fields of nephritis and hypertension, and it is gratifying to note that all the recent advances have been incorporated. An attempt has been made to differentiate glomerular and tubular elements in renal failure. Goldblatt's experimental production of hypertension and the surgical treatment of essential hypertension have been discussed in considerable detail. Hypertensive encephalopathy has been thoroughly rewritten. Fetal azotæmia has been admirably discussed in a separate chapter. Among other new additions, may be mentioned the nephrotic syndrome in diabetes, haemoglobinauric nephrosis, experimental production of glomerulo-nephritis, and the treatment of the nephrotic syndrome by concentrated blood serum.

Every chapter is written in a masterly style and every nook and corner of these difficult subjects discussed in considerable detail. The book not only gives one the idea of what we know but also of what we do not know. The chapter on renal and hypertensive disease in pregnancy is worth special mention. It has been rightly concluded that toxæmia of pregnancy is nothing but latent hypertension becoming manifest as the result of pregnancy, and edampsia is toxæmia of pregnancy plus hypertensive encephalopathy. Fishberg rightly points out that the present-day practice of rigid protein restriction and administration of plenty of fluid to flush out the kidneys is the ideal condition for leading to oedema formation and hypertensive encephalopathy; in other words the chances of eclampsia are enhanced. Obstetricians in this country would do well to read this chapter carefully.

However well a book may be written there is always some room for criticism. Fishberg uses the term 'impairment of renal function', and it seems paradoxical that in chronic nephrosis there is no impairment of renal function even in the presence of massive albuminuria. 'Impairment of concentrating ability' would in the reviewer's opinion be a less confusing term, as this gives an idea of one phase of renal function, i.e., concentration.

It is unfortunate that the omnibus term 'arteriosclerosis' is still being used. Arteriosclerosis includes at least atherosclerosis, diffuse hyperplastic sclerosis and Monckeberg's medial sclerosis. Of these atheroma is a degenerative process independent of high blood pressure but possibly accelerated by high blood pressure; diffuse hyperplastic sclerosis, on the other hand, is the direct result of high blood pressure. Atheroma is usually found in cases of hypertension not because of any causal relationship, but because both the diseases occur at the same age period. Much confusion has arisen and it is desirable that the term arteriosclerosis be omitted and replaced by appropriate terms as far as practicable.

Finally, we find no reason for using the term 'angina' for tonsillitis. There are several printing mistakes which we hope will be corrected in the next print.

These comments are made not with the idea of discrediting the book in any way, but simply as constructive criticism to enhance the value of the book.

It goes without saying that this book is the best of its kind in the English language and should be in the hands of every serious student of medicine. The binding, printing and get-up of the book are beyond criticism.

T. R.

MODERN DRUGS IN GENERAL PRACTICE.—By Ethel Browning, M.D., Ch.B. 1940. Edward Arnold and Company, London. Pp. vii plus 236. Price, 10s. 6d.

DR. ETHEL BROWNING is a versatile writer; the last book of hers we encountered was a very large tome on the vitamins. She shows courage in the choice of her subjects because a book of any size on the vitamins must necessarily be out of date before it is completed. The same remark applies, with perhaps less force, to a book on modern drugs; this however is a short book and the authoress has managed to keep pretty well up to date with her subject. An exception is the omission of any details regarding sulphathiazole, a drug that has now been in use, in America at any rate, for some time, and is proving to be one of the most valuable of the sulphanilamide (*sensu lato*) group of drugs.

The conception of this book is a good one and does not need the apology with which the preface opens; war or no war, patients still require treatment. The execution is also masterly (if this is the right adverb in the circumstances). The compilation of the data from various sources has been carried out very carefully and presented concisely, and it makes an ideal book of references for the practitioner.

The subject-matter is arranged more or less on a pharmacological basis. Proprietary, as well as non-proprietary, drugs are included, but, as the writer has observed (twice) in the preface, of the former only those whose reputations have been established by reports in medical journals have been included.

The book constitutes a valuable addition to the practitioner's library.

A TEXTBOOK OF OPHTHALMOLOGY.—By Sir W. Stewart Duke-Elder, M.A., D.Sc. (St. And.), Ph.D. (Lond.), M.D., Ch.B., F.R.C.S. Volume III. 'Diseases of the Inner Eye'. 1940. Henry Klimpton, London. Pp. xxviii plus from 2097 to 3470, with 1,140 illustrations, including 164 in colour. Price, 70s.

THIS is the third volume of this stupendous textbook which comprises 1379 pages with 1,140 illustrations including 164 in colour.

It maintains the same high standard as the previous volumes, and deals with the uveal tract, the retina, the optic nerve, the lens, the vitreous body, glaucoma and hypotony, and finally intra-ocular parasites.

The whole volume makes most delightful reading, but of special interest to ophthalmologists working in India are the chapters on the anomalies of intra-ocular pressure and diseases of the lens, as he comes across so much of this in the ordinary routine of his work and so much blindness is due to glaucoma and cataract.

Duke-Elder discusses admirably in great detail the important subject of the surgical treatment of glaucoma and in his summing up of the operative treatment of chronic glaucoma states that in the recent past that Elliot's operation was particularly favoured in England and America within recent years, but in India the Elliot operation is tending to fall out of favour on account of latent infection, hypotony and secondary cataract, and the operation of sclerecto-iridectomy by various modifications is now more commonly done.

We have nothing but admiration and praise for this work and again congratulate the author on the

magnitude of his task. Needless to say, we strongly advise and recommend every medical man in India interested in eye work to obtain this book as quickly as possible. As a reference book within the English language it makes most others fade into insignificance.

E. O'G. K.

A GUIDE TO OPHTHALMIC OPERATIONS.—By J. Bruce Hamilton, M.B., Ch.M. (Syd.), D.O. (Oxon.), D.O.M.S. (Lond.), F.R.A.C.S. 1940. H. K. Lewis and Company, Limited, London. Pp. xv plus 201. Price, 10s. 6d.

THIS book of some 200 pages comprises the lists of instruments, drugs and requirements for most of the operations in eye work, together with a foreword by Sir James William Barrett, the doyen of Australian ophthalmology. The pre-operative and post-operative treatment are also discussed.

The author has intended the book primarily for the ophthalmic surgeon and his staff working in private hospitals, and nursing homes, but it will also be found most useful for the staffs of big ophthalmic hospitals, as there is probably no branch of medicine which demands such attention to detail, and such care and gentleness as ophthalmology, both for doctor and nurse if one is to obtain the best results.

The book is excellent and fulfils a distinct want in ophthalmic literature, the author is to be congratulated on his industry and attention to detail.

For India we would like to see the Webster mucous graft operation for cicatrical entropion and the fascia lata graft for ptosis included.

We would like to bring this simple little book to the notice of all hospitals in India in which eye work is done. It will be found invaluable as a guide and help, and we strongly recommend it for all the practical information it contains.

E. O'G. K.

THE ANATOMY OF THE EYE AND ORBIT: INCLUDING THE CENTRAL CONNECTIONS, DEVELOPMENT AND COMPARATIVE ANATOMY OF THE VISUAL APPARATUS.—By Eugene Wolff. Second Edition. 1940. H. K. Lewis and Company, Limited, London. Pp. x plus 374, with 242 illustrations. Price, 31s. 6d.

THIS is the second edition of this book which is written to present the structure, development and comparative anatomy of the normal eye in conjunction with some of their clinical applications. It consists of 367 pages with 242 illustrations and is divided into ten chapters in which the author describes the bony orbit and the accessory sinuses of the nose, the eyeball, the appendages of the eye, the normal appearances as seen with the slit lamp and corneal microscope, the extrinsic muscles of the eye, the nerves, the visual pathway, the vessels, the development of the eye, and finally the comparative anatomy.

In the second edition some sixty illustrations have been added, the blood supply of the visual pathway has been rewritten, there is a note on the differential staining of the rods and cones, and something new about the structure of the vessels of the iris.

The book is excellent and there is little to criticize. It is profusely illustrated with excellent drawings and is written in a simple clear style. To every ophthalmic surgeon and student of ophthalmology, we strongly recommend it, as without a sound knowledge of anatomy the art of ophthalmology is impossible and the book supplies a much needed want.

E. O'G. K.

CLINICAL ROENTGENOLOGY OF THE ALIMENTARY TRACT.—By Jacob Buckstein, M.B. 1940. W. B. Saunders Company, Philadelphia and London. Pp. xlvi plus 652, with 525 illustrations. Price, 50s.

THE interpretation of x-ray observations and of the skiagrams of the intestinal viscera is essentially the work of the physician, as it must be done in the light

of the whole clinical picture and of the biochemical and other examinations that have been carried out. He may accept the report of the radiologist, but he should not let it sway his opinion unduly. On the other hand, he will often find that the radiologist has seen points which he has missed; therefore after making up his own mind he should read the radiologist's report very carefully, and be prepared to revise his own opinion.

The physician will find this book invaluable in assisting him to interpret the roentgenological findings in the intestinal tract. He will read for example that '*the diagnosis of duodenitis on the basis of roentgen evidence must be made with considerable circumspection*' (author's italics), and that the beaded appearance of the appendix which he has had pointed out to him by radiologists as evidence of disease, is, in fact, evidence of a normally functioning organ, and much else that will teach him to rely on his own judgment and his clinical findings, and not to be stampeded by an ill-advised radiologist's report.

The sections in this book are, respectively, on the oesophagus, the stomach, the duodenum, the small intestine, the large intestine, herniation of the diaphragm, the gall-bladder and bile ducts, and the spleen, liver and pancreas. There are over five hundred well-selected skiagrams; the normal is given a very fair share of these, and, in those showing some abnormality, relevant clinical operation and/or autopsy notes are given.

In conclusion, it is a book that every physician and surgeon will want to study, and that every practising radiologist should be compelled to read.

PRIMITIVE TUBERCULOSIS.—By S. Lyle Cummins, C.B., C.M.G., LL.D., M.D. 1939. John Bale Medical Publications Limited, London. Pp. 213. Illustrated. Price, 10s. 6d.

The author, who has lately been David Davies Professor of Tuberculosis, Welsh National Medical School, and whose work on the epidemiology of tuberculosis is well known, has assembled in this extremely interesting book, not only his first-hand knowledge about tuberculosis in Europe, Egypt, Africa and Burma, but also extensive references on the subject from other countries.

The title of the book refers to tuberculosis among 'primitive' communities or communities 'which continue to live in their old tribal tradition, to employ primitive, instead of modern methods, in their pastoral, agricultural or military occupations, to retain their native customs as to property, marriage, education, food and barter, law, order and discipline, habitations and "taboos" costume and language, as opposed to the adoption, from foreigners, of the weapons, machinery, coinage, religion, social outlook and occupations of modern civilization'. This, in fact, refers to isolated and non-industrialized communities. It is well known that, with increasing industrialization and wealth, the standard of living improves and with improved communications the differences between isolated and urban communities fade. Well-isolated communities like the Central Africans and the aboriginal tribes in India may come under the connotation of 'primitive' communities, but it will not be apt to say the same thing with regard to a large part of China and India where tuberculosis has been prevalent in crowded communities for many centuries, although the introduction of the machine age from the West has intensified the complexity of the picture.

The book will be of very great interest to all tuberculosis workers, particularly those dealing with tropical countries and isolated communities. The literature on the subject has been critically reviewed and the author has drawn balanced conclusions therefrom. The complicated but fascinating subject of hypersensitivity and immunotherapy in people of isolated communities has been well expressed in the following paragraph:

'Being quite unacquainted with the tubercle bacillus or only "acquainted" during a few generations, the "primitive", when brought into contact with that germ, tends to become extremely hypersensitive, to break down easily into an acute form of the disease,

and to suffer from a high mortality, especially when brought, further, into the industries or the separations which follow upon his association with the white man. On the other hand, he will, when left in his village, either die quickly or become a "chronic" case, the latter being at first uncommon but becoming much more frequent as the tribe becomes more immune. If civilization continues to obtrude itself on the reluctant "primitive", it will lead to much slaughter of the least immune but will, in the end, reach a state when the immunity will become partially established, as now amongst the white men.

The author thinks that 'for some time to come the "primitives" and their less primitive descendants will react, as they do at present, to tuberculin and tuberculosis, as to a new stimulus; to tuberculin by the exhibition of hypersensitivity and to tuberculosis by severe reaction'. It will, therefore, need several generations of 'exposure' to infection and the slaughter of the susceptibles before a level of relative immunity, comparable to that of highly industrialized western European communities, can be attained. A clear conception of these factors will undoubtedly fortify the epidemiologist, the pathologist, the clinician and the sanitarian with the necessary background for the interpretation of his findings.

The author has ably discussed the various explanations which are offered to explain differences in the response of the tissues to infection and relative immunity—a subject not yet very well understood. It has been shown in several countries that a pronounced sensitiveness to tubculo-toxin and a low immune status are often combined together in principally agricultural populations and that they may account for the nature of the pathological changes met with there. Social factors, immuno-biological factors and, the author thinks, racial factors play a part in modifying these reactions. All workers may not agree with the author's view that the immunity gained in the ancestors is transmitted to the offspring, making subsequent stocks resistant.

Tuberculosis in India has been given a separate chapter in which the author has endorsed the opinions of several workers, notably Lankester, Ukil, Benjamin and Frimodt-Möller. His recent visit to Burma has confirmed the previous findings of the Indian workers. In dealing with tuberculosis in Burma, the author believes that there is some other factor more important than either food or housing, the tuberculosis mortality not corresponding to the worst houses and that this factor is the low resistance to tuberculosis through the many generations of Burmans which have experienced a relative absence of the germ.

The subject of prophylaxis of tuberculosis by means of B.C.G. vaccine has received attention in a separate chapter devoted to it. It had already been pointed out by Indian workers, notably Ukil, that there was a good field for trial of this vaccine to populations which migrated from rural and isolated communities into towns and industrial areas.

The select bibliography at the end of the book will prove useful to workers interested in the subject.

The author, who has been interested in epidemiological problems ever since the early years of the present century, is to be congratulated on the production of a book which is of absorbing interest, is written in pleasant language and is replete with facts and personal observations. Every medical practitioner ought to profit by a perusal of such a book.

A. C. U.

TUBERCULOSIS OF THE UPPER RESPIRATORY TRACTS.—By F. C. Ormerod, M.D. (Manch.), F.R.C.S. (Eng.). 1939. John Bale Medical Publications Limited, London. Pp. viii plus 215. Illustrated. Price, 21s.

GENERAL physicians, tuberculosis workers and laryngologists owe a debt of gratitude to Dr. Ormerod for bringing out such a comprehensive account of some of the difficult complications of pulmonary tuberculosis and for giving a well-balanced view of diagnostic and

therapeutic methods, based on his 16 years' contact with the throat and ear department of the Brompton Hospital, London.

The book is divided into four sections—tuberculosis of the (a) larynx, (b) pharynx and its associated structures, (c) nose, accessory sinuses and nasopharynx, and (d) ear. One hundred and thirty-six out of 215 pages have rightly been devoted to the important subject of tuberculosis of the larynx, including a chapter on Impus of the larynx. Besides a short historical note, each section deals with the aetiology, pathology, symptomatology, diagnosis, prognosis, treatment, and end-results of the different conditions. Each of these aspects of disease has been ably dealt with and, where methods of diagnosis or treatment are concerned, their relative value has been emphasized by the recording of the author's own experience. The illustrations are nicely executed and well reproduced.

A very useful reference has been made to the value of tomography in the detection of laryngeal lesions. We agree with his views that although 'radiography is, in its usual form, of little or no help in the investigation of tuberculosis of the larynx', the introduction of tomography has provided a means for demonstrating lesions particularly in the hidden territory below the vocal cords and the extent to which a lesion has extended downwards into the subglottic regions.

The author has put together much valuable information and experience in this handy volume. The select bibliography at the end of each chapter adds to the value of the work. The paper, printing, and get-up do credit to the publishers.

A. C. U.

ARTIFICIAL PNEUMOTHORAX: ITS PRACTICAL APPLICATION IN THE TREATMENT OF PULMONARY TUBERCULOSIS. CONTRIBUTIONS BY SARANAC LAKE PHYSICIANS TO THE STUDIES OF THE TRUDEAU FOUNDATION.—Edited by E. N. Packard, M.D., J. N. Hayes, M.D., and S. F. Blanchet, M.D. 1940. Henry Kimpton, London. Pp. 300. Illustrated with 85 engravings. Price, 21s.

THE volume represents a contribution by 17 Saranac Lake physicians to the studies of the Trudeau Foundation and deals with artificial pneumothorax (AP) and its practical application in the treatment of pulmonary tuberculosis; it is edited by an editorial committee consisting of Drs. Packard, Hayes and Blanchet, and contains a foreword by Dr. E. R. Baldwin. There is a melancholy touch with its publication inasmuch as Dr. Blanchet, who was a member of the editorial board and Dr. Lawrason Brown, who first conceived the idea of such a publication, both died before the book appeared in print.

In spite of the somewhat disappointing late results of treatment of pulmonary tuberculosis by AP, it is acknowledged that it constitutes, along with rest and time, one of the best weapons to combat the disease. While the beginner in collapse therapy should be well acquainted with the indications and contra-indications for it, including the complications during its induction, the experienced specialist should know what had been the results of continued observation of a varied group of patients in the hands of eminent workers at a well-known centre like Saranac Lake, where ample clinical, laboratory and x-ray facilities were available. Physicians who have to treat tuberculosis will find sound guidance for their work in the present volume.

In addition to the chapters on artificial pneumothorax, the consideration of collateral subjects like the heart in artificial pneumothorax, oleothorax and the applications of other methods of collapse therapy has made the book more useful to general, as well as tuberculosis, physicians. The final chapter is rightly devoted to consideration of the results of treatment by AP. Each chapter is replete with useful information and hints. It is not possible to deal with them in this short review. Artificial pneumothorax is so extensively used to-day in the treatment of pulmonary tuberculosis that the publication of a practical guide like the present

volume has removed a long-felt want. The value of the subject-matter has been enhanced by the inclusion of a useful bibliography at the end of each chapter.

The book has been well produced and does credit to the publishers.

A. C. U.

PHARMACOLOGY.—By J. H. Gaddum, S.D., M.R.C.S., L.R.C.P. 1940. The Oxford University Press, London and New York. Pp. xv plus 407. Illustrated. Price, 17s. 6d. Obtainable from Oxford University Press, Bombay and Calcutta

THIS is certainly a very unusual book and seems to call for an unusual review.

We are, we hope, sufficiently far away to avoid direct reprisal for any personal remarks about the author. We visualize him as a comparatively young man of North country origin with a scientific bent, who only qualified in medicine because his scientific leanings were towards medical science and not because he had any intention of practising. He has made a special study of certain aspects of pharmacology and he rather despises the medical man, especially in embryo, who has to learn such a little about such a lot of subjects, so he throws him little bits of pharmacological information which he can take or leave as he likes, but that is all he is going to get! He is we should imagine a good teacher with a clear and direct manner of expression, but with a distinct weakness for trite remarks.

So much for the writer.

The first chapter is on diet and deals with water and the inorganic salts, calcium and hyper- and hypocalcaemia, and fats. The next chapter is on vitamins; it contains a great deal of concise, up-to-date, and useful information on the subject, and the same may be said of the next two chapters, on hormones, which are divided, rather usually, into those of known and those of unknown structure. Chapters 5, 6, and 7 are on the central nervous system, stimulants, and depressants including narcotics.

Chapter 8 is on body temperature. The next eight chapters deal with systems, or parts of systems, sensory nerves to respiration. The rest of the chapter headings do not seem to follow any particular line of thought and are on proteins, heavy metals and metaloids, drugs that destroy life, chemotherapy, metazoa and bacteria, and there is a final chapter on general pharmacology.

Our only criticism is that the author has allowed his conciseness to carry him too far; it is a mistake on the right side from the student's point of view, but it leaves the reader the task of trying to follow the author's line of thought in order to work out his cryptic remarks. When he says, of phenolphthalein that 'it may do harm when distributed in chocolates amongst irresponsible people', one's mind has to jump suddenly from the pharmaceutical laboratory to the chemist's shop and the advertisements in the daily paper.

He writes, under the heading 'malaria', 'over a quarter of the people of the world suffer from malaria and they consume 600 tons of quinine annually, which is not enough'. This is excellent, because it is so true. But when he writes of tetrachlorethylene, 'Many thousands of men and women have been treated with it; there have been no fatalities among the patients, but unfortunately no one knows how many fatalities there have been amongst the worms' his triteness is merely silly, because the statement is untrue.

However, taking it all round, it is a book that the student will find very helpful and the information in it is certainly enough for any ordinary examination purposes: the specialist will want more complete information, but there are plenty of books where he can get it, whereas the student will find few books that will meet his needs as well as this one. We also recommend it strongly to teachers of pharmacology in India.

PERSONALITY AND MENTAL ILLNESS: AN ESSAY IN PSYCHIATRIC DIAGNOSIS.—By John Bowlby. 1940. Kegan Paul, Trench, Trubner and Company Limited, London. Pp. xii plus 280. Price, 10s. 6d.

THIS is another of quite a number of books published in the last few years which proclaim the emergence of a radical change of outlook in psychological medicine. As such, if for no other reason, this book will be welcomed by all those to whom this change of outlook appeals. The essence of this change is that the psychopathic individual differs quantitatively not qualitatively from the so-called normal person. In other words, all mental symptoms, whether major or minor, always involve the total personality. No intelligent psychiatrist to-day would take exception to Dr. Bowlby's contention that the divorce of mental symptoms from the personality as a whole has been responsible hitherto for the use of an outstanding symptom as a diagnostic label. Hence psychoneuroses and psychoses should come now to be regarded as individual variations of personality. The author, while impressed by the work of Kretschmer and Bleuler, both of whom showed that the personalities shown by schizophrenes differ in many respects from those shown by manic-depressives, goes one step further by attempting to show how it may be possible not only to predict the type of psychosis or psychoneurosis from which any one person might fall in, but to make a fairly accurate estimate of his chance of recovery. The book is provided with a good bibliography and a satisfactory index.

THE DIABETIC LIFE: ITS CONTROL BY DIET AND INSULIN. A CONCISE PRACTICAL MANUAL FOR PRACTITIONERS AND PATIENTS.—By R. D. Lawrence, M.A., M.D., F.R.C.P. (Lond.). Twelfth Edition. 1941. J. and A. Churchill, Limited, London. Pp. ix plus 246, with 18 Illustrations. Price, 9s.

We have great pleasure in reviewing the 12th edition of Dr. Lawrence's *Diabetic Life*. That the book is extremely popular is evident from the fact that within a period of 17 years it has undergone 12 editions.

No fundamental changes has been made in the present edition, except that a few alterations of practical importance have been made in some sections and that a loose page has been added on the war-time precautions for diabetics.

There is a small point, however, referred to by us previously and partially modified by the author, since that requires, in our opinion, still further modification. We are disinclined to agree with the statement of the author that 'The Bengalees and other Southern Indian races who live mainly on rice are very prone to mild diabetes'. Our observations on Indian diets generally and Bengalee diet particularly clearly indicates that rice-eating does not, by itself, act as a contributory factor of diabetes in India.

It is significant that in spite of war-time rationing, the author has thrown out important suggestions for the modification of diet according to the prevailing conditions, the more important among these are the use of vitaminized margarine to replace butter, which is almost of equal value to diabetics. By giving up the sugar ration, diabetics can now receive an extra meat ration and two extra fat rations (12 oz.) per week, a doctor's certificate being required by the food office.

Amongst the war-time precautions for diabetics, particularly during air raids, the author suggests that severe cases of diabetes, who cannot do without big doses of insulin without getting acidosis, should always carry insulin and a syringe with them. They should also carry a small supply of concentrated carbohydrate food, such as sugar, chocolate, or biscuits in their pockets; so that if the regular timing of meals is upset enough carbohydrate can be eaten to balance the insulin.

We earnestly hope that the book will continue to be as useful and as popular as its predecessors.

MAY, 1941]

ABSTRACTS FROM REPORTS

DELTAIC FORMATION WITH SPECIAL REFERENCE TO THE HYDROGRAPHIC PROCESSES OF THE GANGES AND THE BRAHMAPUTRA.—By C. Strickland, M.A., M.D. 1940. Longmans, Green and Company, Limited (17, Chittaranjan Avenue), Calcutta. Pp. xiii plus 157. Illustrated

The day is long past when the physician was expected to have a deep knowledge of all scientific subjects and was prepared to write books or papers on such diverse subjects as ornithology and geology. Is this because, as a profession, we are being made of poorer stuff? Or is it that our estimate of the word *deep* has undergone a profound change, and that a hundred years ago scientific knowledge was so shallow that anyone who scratched the surface could claim special knowledge, whereas to-day the physician has so much to learn about his own subject that he cannot hope to go beyond this? We sincerely trust that our second explanation is the true one, but no one who allows himself to ponder over these matters can fail to feel some slight misgiving at the present trend towards extreme specialization in scientific knowledge. It is therefore with very great pleasure that we have received a book by a doctor, recently retired from a professorship in a medical institution, on a subject that is essentially a geological one.

There is, of course, a link between Professor Strickland's specialty, medical entomology, and the subject of his book, deltaic formation; this is provided mainly by that arthropod-enemy no. I, the mosquito, and it was during his expeditions into this enemy's domains that the author made most of the observations on which this book is based.

It would be wrong to say that hitherto the subject has been a neglected one, for long before child psychology was taken up seriously by the medical profession, geologists in India were doing far more than merely scratching their heads over their problem children, the wayward rivers of the Indo-Gangetic plain, who will never make up their minds which way they want to go and who, when you build them nice bridges to pass under, insist on going round them, but little has been written on delta formation, certainly very little that the ordinary educated man can understand. No one who has any interest in this subject, direct or indirect, can fail to appreciate this little book. Each step is

clearly explained, the whole story is unravelled before the readers' eyes in Dr. Strickland's pleasant style, and where any obscurity might exist this is clarified by the aid of simple diagrams. The book also contains a number of interesting and relevant photographs.

As a mild criticism we might add that the author has a style which though pleasing, as a whole, exhibits a tendency towards obscure constructions and archaic forms. Also, the geologist may complain about some of his terminology, but to the average reader this will be the contrary to a defect.

Above we deplored the extreme tendency to specialization in science, but there are signs that the tide is turning and schools of hygiene include lectures on geology in their programmes; a book on such a subject as the physical condition and the formation of deltas, especially relating to a country like Bengal, where the subject is discussed daily by politicians, sanitarians, economists, and the man in the street, in relation to the problems of the province, is not only the natural outcome of this trend of interest, but should be welcomed by people of all classes.

AIDS TO ANATOMY (POCKET ANATOMY).—By Professor E. P. Stibbe, F.R.C.S. Tenth Edition. 1940. Baillière, Tindall and Cox, London. Pp. vii plus 369, with 50 illustrations. Price, 5s.

It is rather difficult to assess the value of 'Pocket Anatomy' in these days when the achievement of success in learning anatomy no longer lies in the mastery of the details. The teaching now is directed—and more profitably so—towards its bearings on clinical studies. But, nevertheless, a synopsis of such relevant anatomical facts appears to have its field as an aid to the students in their attempts to control the multitude of facts studied from voluminous texts. To render real service, such books must cease to be merely a narrative of bare facts without including clinical relationships.

Professor Stibbe has endeavoured, by way of improvement upon the previous editions, to incorporate in its limited scope, matters having clinical significance. The present volume is, therefore, likely to be much more serviceable than those of the past.

There are one or two mistakes, e.g., in the 'note' on page 74 where 'Hallucis' should be 'Pollicis'.

S. C. S.

Abstracts from Reports

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH. ANNUAL REPORT BY THE CURATOR OF THE LABORATORY FOR THE YEAR 1939

Statistics of anti-rabies treatment.—A ninth analytical review by the superintendent of the results of anti-rabies treatment at the Pasteur Institutes of the world, as deduced from statistics submitted to the League of Nations, is in the press. The figures cover a two-yearly period, and relate to the years 1936 and 1937, the number of persons treated being 304,525. Of these 797 (0.26 per cent) contracted the disease in spite of treatment. In attempting to assess the relative efficacies of the various methods of treatment employed, recourse has been had to the whole statistics dealt with in the nine successive reviews. The number of persons treated during this period was 1,062,707, of whom 3,540 (or 0.33 per cent) contracted rabies. There seems little to choose between the dried cord, dilution, killed phenol (carbolized), live phenol, Fermi, heated, and killed ether methods of treatment as regards their immunizing properties, whilst a mixed method (dilutions, plus in severe cases the live ether vaccine of Alivisatos) is apparently associated with a reduction of mortality which does not exceed 45 per cent, and may be as low as 3 per cent. On the other hand, the risk

of accident as the result of treatment in the case of treatment by killed vaccines is less than 1 in 7,000, whereas in the case of those treated by living vaccines it is greater than 1 in 3,500.

Statistics of treatment in the Union of Soviet Socialist Republics have for various reasons been separately dealt with. The number of persons treated during the period 1929-1934 is 380,090, of whom 612 (0.16 per cent) died of rabies. The conclusions regarding the efficacies of the different methods of treatment employed are in general accordance with those found in the main report.

Trichomonas and thrush vaginitis.—This work showed that the commonest cause of leucorrhœa in pregnancy is an infection with *Trichomonas vaginalis*, 37.5 per cent. Next in importance is an infection with the thrush fungus *Oidium albicans*, 24.5 per cent. In a few cases both parasites were present. Both these parasites have been studied in detail and the various micro-organisms associated with them in the vagina have been noted. The latter possibly play some part in influencing the course of confinement and the puerperium. It is certain that the thrush fungus in the vaginal secretion of pregnant women may communicate infection to their infants and thus give rise, in certain circumstances, to serious mortality among them. The true cause of the mortality is often overlooked.

and attributed to diarrhoea, vomiting and bronchopneumonia.

In studying the conditions which conduce to the development of vaginal infections, attention has been directed to the hydrogen-ion concentration of the vaginal contents. It has been shown by Oberst and Plass that the hydrogen-ion concentration of the vaginal contents is not materially altered by limited dilution with neutral water. These workers had made determinations on eighteen specimens of vaginal discharge, comparing the undiluted pH readings with diluted specimens obtained by washing out the vagina with 15 c.c.m. of neutral distilled water. They found that the wash fluid usually, but not invariably, showed a pH somewhat lower than that of the undiluted discharge, and they concluded that for general purposes the pH of the wash fluid may be more accurate than the reading obtained by small undiluted portions of the discharge.

Using a special pipette the following characteristics of the vaginal contents of normal pregnant women were established. (1) Epithelial cells are almost always more numerous than pus cells. (2) At least half, but generally a larger number, of the epithelial cells are well filled with glycogen. (3) The hydrogen-ion concentration of the vaginal contents is always lower than 5, more often about 4. (4) Döderlein's bacillus is present in large numbers to the almost complete exclusion of other organisms. These findings suggest the existence of a complicated protective mechanism. In contrast, the following findings were established as characteristic of leucorrhœa in pregnant women. (1) The vaginal contents showed that pus cells were present in larger numbers than epithelial cells. (2) The epithelial cells were relatively deficient in glycogen when compared with the normal and this was particularly noteworthy in *T. vaginalis* infections. (3) The hydrogen ion concentration was generally higher, around 5, in thrush infections and around 6 in trichomoniasis. (4) Döderlein's bacilli were more or less completely replaced by other organisms, less markedly in thrush infections, more definitely in trichomoniasis where a great variety of organisms are found.

Chemistry of vaginal discharge.—These fundamental facts in regard to vaginal infection are being investigated further. It has been recognized for some time that the acid reaction of the vaginal contents is related to the presence of lactic acid. Little quantitative work, however, seems to have been done on the lactic acid content of the fluid, and it is not known to what extent differences of lactic acid concentration account for the differences in pH observed.

From a knowledge of the lactic acid content of the washings, and the percentage of discharge they contain, it is easy to deduce the lactic acid content of the discharge. The pH value of the discharge may be taken as that of the washings. A considerable number of fluids have been examined from various conditions, including several normals. Although there is a tendency for fluids of high pH values to contain unusually small amounts of lactic acid, the relationship is not a strict one, and factors other than the lactic acid content are apparently of importance in determining the pH. It is hoped that the investigation will shed light on the nature of these factors, and their relation to the clinical condition.

Additional *in vitro* experiments on the action of various oils upon bacteria suspended in them were carried out. Improvements were made in the methods of suspending the micro-organisms in the oil and of estimating quantitatively the amount of peroxides in an oil. With these improved methods it was found that liquid paraffin had no influence upon the vitality of bacteria for 35 days (which was the limit of the experiment), olive oil killed bacteria in from 7 to 10 days, cod-liver oil in 17 to 22 hours, irradiated cod-liver oil in 1 to 3 hours, and linseed oil in 1 to 1½ hours. It was further found that the amount of peroxides in these oils was proportional to the bactericidal power (*i.e.*, inversely proportional to the length

of time during which bacteria survived being suspended in the oil).

ANNUAL REPORT OF THE CENTRAL CO-OPERATIVE ANTI-MALARIA SOCIETY LIMITED FOR THE TWENTIETH YEAR HELD AT THE ALBERT HALL, CALCUTTA, ON 23RD MARCH, 1940

THIS report does not lend itself to abstraction because the main part of it, which is the report of the secretary, is a review of anti-malarial work in various parts of the world, and is written for laymen interested in the subject.

A list at the beginning, however, gives an indication of the remarkable growth of the movement begun in 1917 when two societies were formed. The actual date of the commencement of the Co-operative Society was 1919 and since then, when four societies were in being, it has steadily grown until now there are 2,362 societies in Bengal of which 1,019 are registered.

The annual general meeting was held on 23rd March of this year when many prominent persons attended, several of whom made interesting speeches. Sir Malcolm Watson was elected president for the second time, having first occupied this position 11 years ago. His address is full of interest to those interested in malaria control for it gives an outline of what has been achieved in malaria control in the many parts of the world where the Ross Institute, of which he is the Director, carries on this work.

ANNUAL PUBLIC HEALTH REPORT OF THE DELHI PROVINCE FOR THE YEAR 1939

CLIMATOLOGY

THE total rainfall for the year was 17.66 inches, which is 10 inches below normal, and exceeds that of the previous year by 4.99 inches. Throughout the year it rained only on 33 days. The highest monthly mean temperature was recorded in May with 94.9° and during this month the highest temperature level of 114° was reached on one day. The lowest figure recorded was 37° in January only. The widest diurnal range was recorded on 16th April when the maximum temperature was 98° and the lowest 63°—a range of 35°. The highest mean humidity was 70 per cent recorded in July and the annual mean 51 per cent, both figures showing difference from those of the previous year, namely 86 per cent and 56 per cent, respectively.

VITAL STATISTICS

Population.—The estimated mid-year population was 732,005.

Births and deaths.—This year showed (a) an appreciable reduction in the number of births with a corresponding fall in the birth rate; (b) a rise in the infant mortality rate; (c) a fall in the maternal mortality rate; and (d) a slight reduction in the death rate which on the whole is steady.

CHIEF CAUSES OF MORBIDITY AND MORTALITY

Smallpox attacked no less than 1,098 persons of different ages during the year under review, and accounted for no less than 606 deaths.

During the year primary vaccinations and revaccinations have risen respectively from 32,857 and 131,784 to 35,862 and 206,867. The improvement in vaccination during the last three years has been very remarkable. This has been obtained by:

- (a) vaccination throughout the year instead of in the winter season only;
- (b) making vaccination the regular duty of all those who are qualified to perform the operation, particularly the maternity and child welfare staff and school medical officers; and
- (c) the revaccination of all children on admission to school (*i.e.*, at the age of 5).

Cholera

At the beginning of November, a sharp outbreak of cholera occurred which was localized to the Sadar Bazar area of the city. And no apparent cause could be discovered for the outbreak. The majority of cases belonged to the Muslim community, at that time observing the fast of Ramzan, and it was thought possible that the evening feasts at the break of the fast were a contributory factor to the spread of the disease.

The health authority in Delhi Municipality took very energetic steps to deal with the outbreak immediately it was recognized and by the first week of December the disease finally died out.

The total number of cases which occurred in the province was 158 with 96 fatalities as compared with 318 and 182 respectively in 1938. Inoculations against cholera were carried out, representing a proportion of 5.33 per cent of the population.

Malaria

There was a further drop in the incidence of 'fever' during the year. How many of these cases can be attributed to malarial infection it is impossible to state, and there can be little doubt that a substantial proportion was due to influenza. However the bulk number of cases of fever has definitely been reduced, and this may be due as much to the failure of the monsoon as to the anti-malaria measures taken. The total amount of quinine and cinchona consumed during the year was 180 lb. and 64 lb., respectively. Assuming that every case of 'fever' reported, had quinine in one or other form, each case had an average of 28 grains. This is a good average.

Plague

The province has again been free from plague.

The cost of rat destruction activities was Rs. 25,335 in the urban area and Rs. 6,579 in the rural area. The rise in the former from Rs. 17,203 in the previous year is largely due to the purchase of a new supply of rat-traps.

Eye diseases

There is a further increase in the number of trachoma cases treated but the ratio of trachoma cases to the incidence of eye disease generally has fallen from 44.32 per cent to 36.21 per cent.

Osteomalacia

The recorded number of cases attending for treatment at the Lady Hardinge Hospital fell from 208 to 194. This variation has no significance.

Cerebro-spinal fever

As in previous years, this disease occurred sporadically. In all, there were 32 cases with a mortality of 69 per cent.

Tuberculosis

The mortality figures were much the same as they were in the preceding year. The figures which are now becoming available from the Queen's Road clinic and from the Rama Krishna clinic, show a distinct rise in the number of cases attending these centres. There have been many important developments in the sphere of tuberculosis during this year.

HEALTH ORGANIZATION*Provincial*

The doctor in charge of the travelling dispensary normally tours by going out to various centres in the rural area and camping there for three or four days at a time. It will probably be found convenient in future to combine the functions of the superintendent, health operations and the doctor in charge as this arrangement will get over the difficulties at present experienced in maintaining a high standard of supervision.

Rural

The main features during the year have been as follows:—

- (a) the progress made in the improvement of rural communications by the building of new roads;
- (b) the progress made in the consolidation of holdings;
- (c) the growing appreciation by the rural population of the services provided by the health organization;
- (d) the continued improvement of water supplies;
- (e) the enlistment of village assistance in the fight against malaria;
- (f) the growing improvement of rural housing;
- (g) the marked improvement of environmental hygiene in the villages;
- (h) the greater measure of co-operation between beneficent departments in the province through the agency of the Central Officers' Board;
- (i) the growing realization by the villages of the value of vegetable cultivation which is evident from the larger areas cultivated this year in comparison with the previous one.

A pamphlet of instructions in vegetable growing in Urdu has been prepared and has had a wide circulation.

- (j) the complete solution of the fly breeding problem at Okhla Sewage Farm.

No less than 67½ miles of new roads have been completed or partially completed at a total cost of over 10 lacs. The influence which these roads exert on health activities, apart from increasing the financial prosperity of the people, is incalculable. The beneficial effect of the new roads has been particularly marked in the Najafgarh health unit area which was rightly given preference in the programme.

The roads are designed to open up the rural area as to an extent which has not been attempted in other parts of India.

The construction of the roads has in itself conferred immediate benefits on the villagers which no health authority could afford to ignore in that, during a year of unusually severe economic distress due to failure of the rains, it has provided the villagers with a much needed means of earning money.

Another most important feature, of particular interest to this department, has been the scientific care exercised during the construction of the roads to prevent the concomitant nuisance from borrow-pits hitherto inevitably associated with road building. For this happy result the province is indebted to the personal interest and whole-hearted co-operation of the Superintending Engineer, Delhi province (Mr. Dean), who has been good enough to explain the method adopted as follows. 'The earth for the embankment was "borrowed" from land temporarily acquired outside the permanent width of land needed for the road. The maximum depth of the borrow-pits was fixed at 1 ft. As soon as the bank was completed to the full height and section required, the land, which had been temporarily taken over, was handed back to the cultivators for ploughing which largely obliterated the depressions caused by the excavation and levelled up the land.'

Of equal importance from the public health point of view had been the achievements of the co-operative consolidation of holdings societies. Up to date 22,325 acres represented by 33,711 blocks with an average area of 0.66 acre per block have been consolidated into 6,865 blocks with an average area of 3.325 acres. What this means to the public health department is the increase in the productive capacity of the land and, therefore, in the prosperity of the individual; the provision of *shamlat* (or common land) on which such vital necessities to the health of the villages such as refuse disposal pits, latrines and playing grounds can be sited; and the conversion of 412 acres of *barani* land into *shahi* by the sinking or transfer of wells which made it possible for vegetables to be cultivated.

An innovation of some importance in the practical education of villagers in their responsibilities as custodians of their own health has been the enrolment

in each village of 'malaria guards' charged with the important duty of guarding their village from the ravages of the mosquito. Their work, under the supervision of the health staff, consists in the levelling and filling of ground around their villages and in making it as difficult as possible for the vector to breed within an area which can harm them. The 'guards' have been presented with badges which they display with great pride, not matched in every case by their keenness to work, but there is every reason to hope that the movement will gather momentum and will prove in time to be a really effective instrument in the fight against malaria in the rural area.

An instance of the astonishing ease with which a village may fall from grace merely through 'pique' is provided by the fact that the winning village in last year's 'best village' competition has temporarily lost all interest in its betterment merely because the villagers felt they had been thwarted in the manner in which they wished to spend the prize money. There is every hope that this matter will be satisfactorily adjusted but the incident leads one to suspect that in this village at least, appreciation of village improvements has been rather superficial and not completely disinterested.

Urban

Housing.—An advance of the most outstanding importance has been the acceptance by the Government of the principle that assistance should be given to a population dispossessed by slum clearance to enable them to obtain not only alternative accommodation, but accommodation of a better standard than that from which they have been rejected.

The main difficulty hitherto experienced in India in effective slum clearance has been due largely to the fact that the legislation devised for this purpose has not been as stringent as it is, for instance, in Britain and elsewhere. We in Delhi have to be much more 'gentlemanly', we have to pay for the slum houses and to compensate the owner for depriving him of his means of exploiting human misfortune.

Having got as far as to eject a person from a locality or building declared to be unfit for human habitation, no machinery has existed in India for his being rehoused. If he could afford to build himself another house, facilities were provided for him to do so. Otherwise he just went elsewhere to live in the same squalor in which he had always lived and to create a slum similar to the one which had been cleared. Both in Cawnpore and in Calcutta where Improvement Trusts exist it was found impossible to deal with this problem for the simple reason that very substantial free grants were involved and these were not forthcoming. In England the cost of rehousing the poor has been accepted as a duty by the public and the state, and grants towards rehousing are made both by the central government and the local municipality concerned. Acceptance by the Government of India of this principle is, therefore, an advance of incalculable importance and one which may have the most far-reaching influence on the progress of house improvements and slum clearance in this country.

Under Indian conditions the minimum rent for a house fit for human habitation was assessed at Rs. 5 p.m., and the lowest income which could bear to pay such rent at Rs. 30 p.m. A family with an income less than this has been accepted by the Trust as one which cannot afford to pay for a house fit for human habitation and therefore needs assistance in rehousing.

This standard has been applied to an area in the city selected for slum clearance (Hathi Khana and Ara Keshan) where it has been found that 137 families come within the below Rs. 30 p.m. category.

The next important decision taken has been that of fixing a minimum standard of floor space for each person. Having regard to local circumstances generally this has been determined at 36 sq. ft. per person, no distinction being made for separation of sexes, and a room capacity of not more than three adults (counting two children as one adult) for a single-roomed house, not more than five adults for a two-roomed

house, and three rooms for a family consisting of more than 5 adults. Standard plans for one-roomed, two-roomed and three-roomed houses have been prepared on the basis of a plot of 100 sq. yards. The houses have been so designed as to make it easily possible for a one-roomed house to be converted by addition of rooms, into a two-roomed or a three-roomed house.

The cost will be roughly Rs. 450 for a one-roomed house, Rs. 600 for a two-roomed house and Rs. 750 for a three-roomed house. Now the average rent capacity of the families to be dispossessed is estimated at Rs. 2-13 p.m. while a return of Rs. 3-9 per mensem represents the minimum rent on a no profit basis. This figure includes maintenance at 1 per cent ground rent and repayment of capital plus 4 per cent margin for cost of collection. This, plus the equated instalments of the cost on a 20-year basis, works out to Rs. 5-3-6 per month.

The experiment proposed in Delhi is to make it possible for the poor class families concerned to own their houses on the hire-purchase system. This, besides being a desirable feature in itself as it gives each individual a stake in the land, is calculated to overcome the reluctance experienced in other cities in India for dispossessed families to move into houses built for them. Any family which can pay a rent of Rs. 3-8 p.m. will be admitted to the benefits of ownership through hire-purchase and the difference between what can be afforded and the minimum rent (plus equated instalments) is made up by grants from the proceeds of a special tax imposed by Government, namely, an entertainment tax. •

NAJAFGARH HEALTH UNIT

The main points to be noted on the progress of the unit throughout the year are the following:—

- (i) the growing interest and appreciation displayed by the people in the activities of the health unit;
- (ii) the move of the headquarters office from the house in Najafgarh town to another, granted free of cost by Pandit Raghib Singh of Najafgarh, who has also provided the medical officer of health and lady superintendent with a residential house free of rent and taxes;
- (iii) the appointment of Dr. (Mrs.) Bhatnagar as lady superintendent, maternity and child welfare in place of Miss Jessie Smith, retired;
- (iv) the growing importance of the health unit as a demonstration unit for students and as a controlled area suitable for research;
- (v) the improvements in communications, in vital statistics, in sanitation, in protection against smallpox, in maternity and child welfare and in the care of the school child.

Beside Pandit Raghib Singh's gift, Pandit Ram Krishan of Paprawat has offered to build a centre to take the place of the existing hired house at Najafgarh. Unfortunately it has been impossible so far to make use of this generous offer owing to the lack of a suitable site, but the offer is still open. These gifts, though not by themselves proof, undoubtedly reflect the general appreciation by the public of the services provided by the health unit. The only section which may still be described as sullen and unmoved is Dandasa, but even here there have been encouraging signs lately of growing interest.

No minor part of the function of the health unit is the facility it affords for the training of students, medical or lay, and the fullest advantage has been taken of this facility throughout the year. Parties of students from the Lady Reading Health School and the Lady Irwin College each attended a specially arranged course lasting over a week during which they had the fullest opportunity of studying at first hand life of the villagers, the duties and functions of the skilled workers appointed to assist them, the organization of the health unit and the value or co-ordinated social services. A day tour was also arranged for the senior students from the Lady Hardinge Medical College. The Medical Officer of Health also fulfils the very important function of teaching the pupil teachers at

MAY, 1941]

ABSTRACTS FROM REPORTS

the normal training school, Najafgarh, all that is practical and important in hygiene and sanitation as applied to Indian village conditions, to schools and their environment, and to school children.

Fifteen villages in the health unit area were provided with radio sets and these pick up the rural programme broadcast from Delhi for an hour every evening. The villagers display the greatest interest in the broadcast and there can be no doubt of the value of this means of education and propaganda in all matters affecting the villagers' life.

ANTI-MALARIA OPERATIONS IN DELHI URBAN AREA, 1939

BY

Lieut.-Colonel G. Covell, C.I.E., I.M.S.,
Director, Malaria Institute of India

As has been the case since 1936, malaria control measures in the urban area have been carried out under the direction and supervision of the Malaria Institute of India.

As regards permanent engineering works, the total sum sanctioned for this purpose in the financial year 1928-39 was Rs. 7,000. This was devoted to work on the Timarpur Sullage Farm, which had always been a prolific source of mosquito breeding, affecting in particular the Timarpur clerks' colony. The project consisted of three parts: (i) the diversion of sullage water by the construction of a masonry drain discharging into Najafgarh cut; (ii) levelling and dressing the whole area so as to drain it into the cut; and (iii) providing a sluice-gate under a raised roadway, which will act as a bund to prevent water being headed up into the area when the Jumna river is in flood. This project was completed during the year.

No provision was made for permanent works in the 1939-40 budget, but special sanction was given to use a sum of Rs. 34,000, representing savings from the city ditch project, for further very important work on the Bela. This included the raising of the bed of the terminal portion of the city ditch outfall, dressing and draining a triangular area between this and the Power House, raising the bed of the Fort Pukka Nala and fencing both this and Khairati Nala, with the provision of a bridge-crossing in each case. All this work has been completed during the year, representing a marked improvement in the condition of this part of the Bela.

ANTI-MALARIA OPERATIONS IN THE RURAL AREA OF
DELHI PROVINCE

Abnormal weather conditions again prevailed. This made it impossible to assess fairly the value of the various measures adopted in controlling malaria.

Operations in the 3-mile belt

Au overflow channel to the south of Quarry railway line has been provided during the year. Further, a new realignment of Kushak Nullah to the north of Quarry railway line has been taken in hand to drain the Kushak Nullah into the Chirag Delhi drain which it is hoped will be completed during the year 1940-41. During the year under reference a sum of Rs. 16,050 from the funds was made available for this work. Improvement of surface drainage round Rajpur village has not been completed as the land had to be acquired from the owners. The work of filling and draining both sides of the old Najafgarh Road near the Darhalla Nullah has been completed.

Recurring measures were as follows:—

- (i) the issue of quinine for the treatment of malaria cases in 64 villages instead of 60. The four villages lying in the neighbourhood of Pusa Agriculture Institute were included during the year;
- (ii) anti-larval measures, including minor levelling, draining and the application of larvicides in 14 villages including 10 villages south of Quarry railway line and 4 other villages in the neighbourhood of Pusa Agriculture Institute;

(iii) the spraying of adult mosquitoes was carried out in 15 villages as against 11 in the previous year. The quarters and huts lying in the new sewage farm were also included.

The results of these measures were determined by the spleen indices taken at the beginning and at the end of the malaria season (*i.e.*, June and December). For purposes of convenience the villages have been classified in three groups as follows:—

- Group A.*—Villages which had quinine alone;
- Group B.*—Villages which had quinine plus anti-larval measures;
- Group C.*—Villages which had quinine plus adult spraying.

In group A there are 33 villages, 10 in the irrigated tract (north and north-west), 7 in the Bela or north-eastern tract which is subject to inundations from the river, and 16 in the dry tract which is subject to storm water flooding from the Ridge. Of these 33 villages, improvement in spleen index is apparent in 21 or 63.6 per cent; the proportion being 80.0 per cent in the irrigated tract, 43 per cent in the Bela and 62.5 per cent in the dry tract.

In group B there are 14 villages of which 10 are in the southern portion immediately south of old sewage farm, and 4 in the west in the neighbourhood of Pusa Agriculture Institute. In this group improvement in the spleen index is apparent in 10 or 71.4 per cent.

Finally there is group C in which there are 16 villages, 6 in the irrigated area, 5 in Bela and 5 in south-east of old sewage farm. The improvement in spleen index is apparent in this group in 10 or 66.7 per cent.

The cost per head of population works out as follows:—

- | | |
|--|-----------------|
| Group A (Quinine alone) | -/2/5 per head |
| Group B (Quinine and anti-larval measures) | -/12/1 per head |
| Group C (Quinine and spraying) | -/5/10 per head |

ANTI-MALARIA MEASURES IN NAJAFGARH

The activities financed by the Indian Research Fund Association grant of Rs. 50,000 spread over five years were continued on the same scale as during the previous year with perhaps greater thoroughness and intensification as greater familiarity with the terrain was established.

The villages which were sprayed in addition to the other measures adopted displayed no appreciable advantage in so far as the reduction of spleen indices in villages not so treated was concerned.

Operations in the rest of the Province

No special personnel was employed outside the authorized health establishment. The measures taken were as follows:—(a) quinine distribution; (b) anti-larval measures including filling, levelling and draining around each village; (c) adult mosquito spraying.

MATERNITY AND CHILD WELFARE

Urban

Progress in New Delhi continues to be hampered by the lack of suitable centres. In the meanwhile owing to the impracticability of making use of the donation of Rs. 20,000 made by the Marchioness of Willingdon for an infectious diseases ward, this money, with Lady Willingdon's permission, is to be used for the construction of the badly needed centre in Jangpura.

In spite of the difficulties under which the Maternity and Child Welfare Services labour in New Delhi progress in many directions continues to be made. This can best be judged by the following summary:—

The number of confinements undertaken by the centres rose from 1,004 in 1938 to 1,218 in 1939. Excluding the confinements in the Lady Hardinge Hospital, the District Jail and in Viceregal Estate, those managed by the centres represent a proportion of 72 per cent as compared with 62 per cent in the previous year; while of the total births in New Delhi,

they represent a proportion of 37 per cent as compared with 38 per cent in the previous year. Attendances at the clinics rose sharply from 26,310 to 35,505 while the number of home visits rose slightly from 31,192 to 31,880. There were no maternal deaths amongst the cases undertaken by the centres—the maternal mortality for the rest of New Delhi was 3.32 per mille.

Only in infant mortality there has been a slight setback, the rate being 75 per mille in 1939 as compared with 65 per mille in 1938. On the other hand this compared favourably with the infant mortality rate for the whole of New Delhi which stands at 85 per mille, in itself a substantial improvement on the previous year's figure of 115 per mille.

Further improvement in the infant mortality rate in New Delhi can only be hoped for if the following conditions are fulfilled:—(i) better centres; (ii) more health visitors; (iii) improvement in the mobility of health visitors.

The centres in New Delhi continue to contribute their valuable quota of vaccinations, 1,183 operations having been performed in 1939, as against 287 in 1937.

Free milk was supplied to 190 indigent mothers. The issue of this important ingredient of the dietary of an expectant mother is fraught with certain practical difficulties.

The income from fees realized in New Delhi was Rs. 2,262 as compared with Rs. 401 in 1936 when the fees were charged on an even basis of 2 per cent of the husband's income. The rates were increased slightly in relation to the means of each individual's income and the return from fees has been rising steadily ever since.

The Mrs. Girdhar Lall Maternity Hospital was opened during the year. This institution although sited in New Delhi is not intended to serve any of the residents of New Delhi.

Rural

The area served by the centres has been considerably widened, and whereas in 1938 the staff of the three centres at Narula, Nangloi and Mahrauli dealt only with 548 cases of confinement, in 1939 they dealt with twice that number, namely, 1,088.

As regards infant mortality, the general rate in the rural area is of the order of 206 per thousand births, but on the other hand the rate amongst babies who are cared for by the centre staff is considerably lower. Maternal mortality amongst cases conducted by the centre staff is reported to be nil.

Delhi Health Society

The two centres maintained by this society at Sahibabad Daulatpur and Alipur continue to flourish and there is ample evidence to show how much they are appreciated by the villagers.

SCHOOL MEDICAL SERVICE

Urban

New Delhi.—The service established in the municipal schools continues to flourish.

There are two noteworthy features, namely, the introduction of inoculations against the typhoid group of diseases and the continued rise in the number of home visits. An explanatory pamphlet was circularized among parents and guardians and 1,756 children out of 2,670 accepted the offer. Of this number 1,238 received one dose and 518 two doses.

The number of attendances for treatment at school clinics in New Delhi has risen from 16,400 to 20,478 boys, and from 15,748 to 16,894 girls.

During the hot weather a special study was made of the effects of heat on school children. It was concluded that there certainly was evidence that the children were being subjected to a severe strain. Municipal Schools in New Delhi are accordingly closing in May and June this year as an experimental measure.

The scheme for the distribution of milk to school children continues with success. The number of school children paying for their milk was 180 as compared with 190 in the preceding year. In addition the Committee provided free milk for 100 indigent children per month, at a total cost of Rs. 1,664.

One interesting feature is the revelation that the greater number of dental defects occur among the more affluent classes than among the poorer classes. The explanation tendered is that the latter eat the coarser, less refined, and therefore less impoverished food, as for instance unhusked rice, coarse wholemeal atta, and potatoes cooked 'in their jackets'. Nothing eaten by the poorer classes is over-cooked, while the water in which vegetables are boiled is not thrown away but eaten.

No less than 579 boys and 603 girls were referred to the eye specialist during the year. Of these 245 boys and 239 girls were found to be free of any condition demanding treatment. The rest attended for treatment on 1,039 occasions, an average of 1.5 visit per case.

Delhi City.—The situation regarding the school medical service in Delhi City remains exactly as it was before.

Notified Area Civil Lines.—The number of attendances at the school clinic for treatment reveal that a very much larger number of girls than boys attended. The commonest complaint among the boys appears to have been minor surgical conditions as one would expect, while the predominating ailment among the girls was respiratory trouble—bronchitis, colds and sore throats.

Rural.—A smaller number of boys but a much larger number of girls attending schools in the rural area were inspected during 1939 than in previous years.

It is a matter of regret that no progress has yet been made in the matter of readjusting the school syllabus so as to include the teaching of hygiene on a compulsory basis if possible, from the earliest classes. The health staff in all areas have been active in lecturing to school children and in improving the sanitation of the schools, drinking water arrangements have been improved in most places and bore-hole latrines have been constructed. The district educational authorities have been very helpful in these improvements.

THE KING GEORGE V TRAVELLING RURAL DISPENSARY

In all, 803 villages were visited during the year and treatment for minor ailments was provided for 12,064 patients. In addition 43 magic-lantern lectures were delivered and the doctor in charge broadcast 3 talks for the village programme from the Delhi studio. Anti-cholera inoculations and vaccinations were performed. The travelling dispensary was also in attendance at the two fairs held in the province.

PROVINCIAL LABORATORY

Work carried out in the laboratory included examination of samples of water, chemicals, clinical material, and food.

The present food supply is 30 per cent adulterated and strict control is badly needed to improve the general health of the public.

ANNUAL REPORT ON THE HEALTH OF THE ARMY IN INDIA FOR THE YEAR 1939

The health of the Army has been satisfactory and there have been no serious epidemics, although civilian areas amidst which troops are placed suffered extensively from cholera, plague, smallpox, dysentery, malaria and enteric fevers.

How vaccination and inoculation, sanitary control of cantonment areas and water supply save troops from smallpox and enteric fever, is seen from the fact that of smallpox there were only four cases in the whole of India amongst British troops and their families and

of enteric fever only one per 1,000 was infected amongst British troops, the incidence among Indian troops dropping to 0.5 per 1,000. Also there were no cases of cholera or plague amongst the military personnel.

Admission rates both for officers and men increased for British troops but the increase was more apparent than real owing to changes of strength.

Although the admission rate of 666.1 per thousand showed an increase of 63 per thousand on the previous year, the death rate and invalidating rate decreased and the quinquennial figures for admissions and deaths continued the fall obtained since 1920.

Amongst British soldiers malaria, sandfly fever and the dysentery-diarrhoea group were prominent. The insect-borne group, malaria, sandfly fever and dengue between them accounted for over 90 admissions per thousand of strength and for an increase of nearly 20 per 1,000 on the previous year. This was due in part to troop movements, early return to the plains and the manning of defensive posts in outlying unhealthy areas.

With an increase in the average of those constantly sick in hospital and an increase in barrack-treatment cases, the number of inefficients increased from 52.27 in 1938 to 53.06 per thousand, but the total loss in working days was considerably less.

Among the principal factors affecting the health of the Army were many of the unusual movements of troops by train or road throughout the hot weather necessitated by the European tension culminating in the war. No casualties resulted from these moves. But an early return to the plains and manning of the defensive posts in unhealthy areas produced insect- and fly-borne infections. Operations in the early spring in Waziristan gave surprisingly low sick rates in spite of cold weather.

Spraying of living quarters as a defensive measure against all insect-borne diseases was further developed, often with success as in the reduction of sandfly fever in Peshawar and Rawalpindi districts. Arrangements were completed for manufacturing pyrethrum spraying solutions in our own medical stores depots from Empire grown pyrethrum flowers from Kenya.

There was no serious epidemic in the Indian Army and the rise in admission rates by 32 per 1,000 to the present figure of 454 per 1,000 is fully accounted for by conditions of war service. Large numbers of reservists returned to their units, hundreds of men returned from leave in and through highly malarious areas, there was a considerable influx of recruits, overcrowding was temporarily inevitable in many barracks, and many defensive posts had to be manned in unhealthy areas. Invaliding rates at 6.43 per 1,000 showed a small increase, but death rates fell to 2.12 per 1,000.

The increase in admission rates was due in great part to malaria, scabies, sandfly fever and the minor respiratory group, common cold and pharyngitis. The death rate of 2.12 per 1,000 continued the steady fall of the past fifteen years. Injuries with over 70 deaths and pneumonia were the commonest cause of deaths.

With the rise in average constantly sick the average sick time per Indian soldier increased but the average duration of each case decreased. The total inefficiency per day at 34.6 per 1,000 was slightly higher than that of the past two years but less than that of 1936.

As for the physical development of cadets in military colleges and schools, failures were few and the monthly increases in weight varied from $1\frac{1}{2}$ to $2\frac{1}{2}$ lb. per boy per month.

Barracks are being improved. The mosquito carrier is being eliminated by drainage, oiling, paris green powder, spraying with insecticides, 'dry day', 'sluicing', and above all by the use of larvicultural fish. Pasteurization of milk is being introduced in Southern and Eastern Commands.

In Northern Command 15 fully organized committees for co-operating with civil authorities are in existence.

Arrangements are being made for the provision of hygiene demonstration areas at every large station to form part of the brigade training scheme. Modern automatic chlorinating apparatus for purifying drinking water has been installed in one or two places.

Correspondence

ANTISEPTIC ANALGESIC TANNIC-ACID JELLY FOR BURNS

SIR.—I wish to put before you that I read an article in the journal edited by you of the month of 'February 1941' regarding the preparation of a jelly for burns given on 'page 121'. We tried to prepare the jelly—according to the formula given, but to our surprise instead of the jelly being formed only a solution was formed. Hence I shall be highly obliged if you will kindly let me know the exact method of preparation of the jelly.

Civil Surgeon.

CIVIL HOSPITAL,

AURANGABAD,

1st April, 1941.

[*Note.*—For tropical countries the percentage of pulv. tragacanth co. should be increased from 2 to 4 per cent. This is usually sufficient to make a more solid jelly; if not, a little agar or gelatin should be added.—EDITOR, *I. M. G.*]

Service Notes

APPOINTMENTS AND TRANSFERS

LIEUTENANT-COLONEL J. P. HUBAN, O.B.E., is appointed Additional Deputy Director-General, Indian Medical Service, with effect from the 28th February, 1941.

The services of Lieutenant-Colonel G. D. Mallioutra, Civil Surgeon, Moradabad, have been placed at the disposal of the Government of India, Defence Department, with effect from the 10th March, 1941.

Lieutenant-Colonel J. M. R. Hennessy, Civil Surgeon, Jubbulpore, has been posted to the Hoshangabad District with headquarters at Pachmarhi.

The Secretary of State for India has sanctioned the reversion to military employment of the following officers of the Indian Medical Service (Civil), with effect from the dates mentioned against their names:—

Bengal

Lieutenant-Colonel B. P. Baliga, 25th May, 1940 (forenoon).

Bihar

Lieutenant-Colonel G. H. Mahony, 9th May, 1940 (afternoon).

Bombay

Major B. S. Sandhu, 7th May, 1940 (forenoon).

The services of Major G. W. Miller are placed temporarily at the disposal of the Defence Department (Navy Branch), with effect from the 8th February, 1941 (afternoon), for employment as Principal Medical Officer, Royal Indian Navy.

On return from leave Major J. H. Boulbee is posted as Civil Surgeon, Agra.

To be Captain (on probation)

Charles Sieveright Gamble. Dated 20th October, 1939, with seniority as Lieutenant from 20th October, 1938, and as Captain from 20th October, 1934.

The services of the undermentioned officer are dispensed with:—

**INDIAN LAND FORCES
(Emergency Commission)**

Lieutenant Niranjan Choudhury. Dated 1st February, 1941.

INDIAN MEDICAL SERVICE (DENTAL BRANCH)

To be Lieutenants (on probation)

1st February, 1941

Mahmud Ahmad.

Raj Sethi.

Kartar Singh.

Sheikh Nazeer Mohammad.

Munawar Qureshi.

Vere Oswald Arathoon.

Joginder Singh.

LEAVE

Lieutenant-Colonel R. F. D. MacGregor, C.I.E., M.C., an Agency Surgeon, is granted an extension of leave on medical certificate for 6 months in continuation of leave sanctioned in previous notification, dated the 5th February, 1941.

PROMOTIONS

Colonel to be Major-General

H. Stott, O.B.E. Dated 23rd February, 1941.

Major to be Lieutenant-Colonel

J. McM. Wilder. Dated 28th March, 1941.

RETIREMENTS

Major-General H. C. Buckley, R.H.P. Dated 31st October, 1940.

Colonel E. S. Phipson, C.I.E., D.S.O., V.H.S. Dated 10th March, 1941.

Lieutenant-Colonel F. J. Anderson, C.I.E., M.C. Dated 10th March, 1941.

Lieutenant-Colonel D. P. McDonald. Dated 13th March, 1941.

Lieutenant-Colonel C. J. Lodge-Patch, M.C., Medical Superintendent, Punjab Mental Hospital, Lahore, who was on leave ex-India till the 18th February, 1941, retired from the service, on medical grounds, with effect from the 19th February, 1941.

RELINQUISHMENT

The undermentioned officer relinquishes his commission on the grounds of ill-health:—

**INDIAN LAND FORCES
(Emergency Commission)**

Lieutenant N. Sitaraman. Dated 5th March, 1941.

Notes

DUST AND DISEASE

Dust is a recognized nuisance. It not only makes road travel extremely uncomfortable and sometimes dangerous, but is also injurious to health.

When blown about in the air, dust is the direct cause of many diseases. Dust infects the nose, throat and lungs, and may convey the causative organisms of tuberculosis, smallpox, dysentery and many other serious illnesses.

The simplest treatment is to water the surface of dusty roads, paths or courtyards. The effects, however, are only temporary and it is impossible to imagine the dust of thousands of miles of mofussil roads being kept down by artificial watering alone.

More permanent methods are to pave with stone slabs, lay cement or lime concrete, or surface with tar or asphalt.

The attention of our legislators should be drawn to this important question and provision made in the budget of every administration for the treatment of dust on roads.

(*Extracts from a circular issued by the Indian Roads and Transport Development Association, Limited, 41, Nicol Road, Ballard Estate, Bombay.*)

'TABLOID' 'EMOCIN' THROAT LOZENGE

AFTER tonsillectomy or in irritative and inflammatory conditions of the throat relief may be obtained by the application of acetylsalicylic acid to the seat of pain. The introduction of Tabloid Emocin by Burroughs Wellcome and Co., provides a newer and more satisfactory means of carrying out this treatment.

Each product contains two grains of Empirin acetylsalicylic acid combined with a flavoured demulcent base. Dissolved slowly in the mouth, Tabloid Emocin has prompt analgesic effect at the site of contact. On absorption, moreover, there follows a more prolonged action resulting from central analgesia.

Issued in tubes of 25.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints gratis; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

The preparation of reprints entails rearranging the type, so that there is often a delay of a month or more, after the publication of the *Gazette*, before the reprints are ready. If reprints are not received within two months of publication of the *Gazette*, contributors should write to the Publishers.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors and of the publishers.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19.8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

A STUDY OF RHINOSCLEROMA IN VIZAGAPATAM

By B. TIRUMAL RAO, F.R.C.S. (Edin.), F.R.F.P.S., D.L.O.
Superintendent and Surgeon, Ear, Nose and Throat
Department, King George Hospital

and

T. BHASKARA MENON, M.D., B.Sc., F.R.C.P.
Professor of Pathology, Andhra Medical College,
Vizagapatam

Introduction

REPORTS regarding the incidence of rhinoscleroma in India are rare, though there is evidence that Chota-Nagpur is a well-defined endemic focus. A case is recorded by Castellani and Chalmers (1919) in an Indian coolie. Another typical Indian case has been figured by De and Chatterjee (1935). It seems probable that cases exist, but have not attracted sufficient attention from Indian workers. In East Asia, the Dutch Indies, especially Sumatra and Bali, are known endemic foci and the Dutch workers, Noosten, Kirschner and Vos (1934), Kouwenaar, Maasland and Wolff (1934), Snijders (1936), Wiclenka (1937), and others regard the disease as affecting particularly ancient primitive indigenous races. An anthropological relation to the Munda and Kolar stock of Chota-Nagpur has been postulated. However, endemic foci are well known in Eastern Europe, particularly in Poland. Notification of scleroma was made compulsory in Poland in 1930 and in six years 562 cases were notified (Zaleswski, 1938). In a general survey in Rumania, 36 cases were found (Metami and Tempia, 1930), mostly from the northern provinces. Cases have been reported from Russia, Germany, Austria, Hungary, Italy and Switzerland. On the American continent cases are met with in very small numbers affecting the whites as well as the negroes. South American foci have also been described. Cases also occur in Egypt and Algiers.

Cases for study

The following six cases encountered at King George Hospital, Vizagapatam, presented a typical clinical picture. In four of these, pathological examination revealed the characteristic histological changes in the tissues besides showing *Klebsiella rhinoscleromatis* that is constantly associated with the disease. Culture was carried out only in one case and it proved positive. Neither the complement-fixation test nor the skin reaction could be carried out. For purpose of histological examination besides routine methods of staining for cell picture, special methods were carried out for the demonstration of the organism in section. These included

Weigert's fibrin stain, Murray-Drew's stain and the methyl green pyronine method.

Case 1.—N. H., Hindu male, *æt.* 40, from Ganjam District, admitted for nasal obstruction of ten years' duration. At first a small lump was found inside the nose at about its middle; this gradually developed in five years. There has also been difficulty in swallowing. The obstruction to breathing through the nose is complete. The pillars of the fauces are so closely approximated that only a narrow vertical slit is left for breathing. The patient takes liquid food with difficulty. A tumour of the size of a small lime, hard, nodular and slightly tender and irregular in outline is present at the philtrum. No laryngoscopy or posterior rhinoscopy could be done. Blood—Wassermann positive +. Nasal accessory sinuses opaque.

Case 2.—P. H., Hindu male, *æt.* 30, from Vizagapatam District, admitted for swelling of the nose and obstruction to breathing of four years' duration. The skin surface of the nose is very uneven and hard; the tip of the nose is very much enlarged. The anterior nares is completely occluded, the upper lip is swollen and hard and the soft palate is similarly thickened. Blood—Wassermann negative. X-ray shows nothing definite except that the ethmoidal cells are opaque.

Case 3.—K., Hindu male, *æt.* 25, from Berhampore, Ganjam District, admitted for swelling of nose of four years' duration with a history of having started with a discharge of pus and blood from the nose. He has been treated with salvarsan injections. The nose is flattened, the bridge broad, hard crusts which bleed on removal are found at the anterior nares which is very much stenosed. Blood—Wassermann negative. X-rays shows no evidence of any affection of bone. Posterior rhinoscopy showed some crusty purulent discharge.

Case 4.—D., Hindu male, *æt.* 24, admitted for swelling of the nose and upper lips of two years' duration, and a history of having started with a growth inside the nose. It then extended outside the nose involving the upper lip in a symmetrical manner. This shows a butterfly-shaped ulcerating granulatory area involving and occluding both anterior nares and upper lip with a nodule in the left nares; soft palate and pillars of the fauces are thickened and hard, the arch is thickened and hard and the upper incisors loose. Posterior rhinoscopy shows a whitish nodular growth protruding from the posterior nares. Indirect laryngoscopy shows lingual tonsil slightly hypertrophied, vocal cords sluggish in movement. Blood—Wassermann positive. X-ray shows both maxillary antra opaque.

Case 5.—P. A., Hindu female, *æt.* 50, admitted for obstruction to breathing through the nose of several years' duration. Alæ nasi, as well as tip, hard, indurated and swollen. The anterior nares is completely occluded. X-ray shows no evidence of involvement of sinuses.

Case 6.—S. S., Hindu female, *æt.* 45, admitted for difficulty in breathing and ulceration of the nose of six years' duration. This started with bleeding from the nose and anosmia. The nose is broadened and flat and the anterior nares occluded. A firm, flat, reddish looking circular rupia-like growth covered with thin scabs is occupying the centre of the upper lip and extending to the dorsum of the tip of the nose; margin raised, - slightly congested and firm; septum not discernible; soft palate hard and adherent to the posterior pharyngeal wall. Blood—Wassermann negative. X-ray nothing definite.

Pathology

The condition has been described as commencing primarily in the nose and spreading later to the nasopharynx or larynx. But the process may originate and remain more or less confined to the nasopharynx, larynx, or trachea. In this series, the origin in all cases appears to be in the nose, involving later the upper lip in all except case 3. The soft palate was involved

in case 4. In case 1 the faucial arch was involved so much, and so reduced by cicatricial contraction that only a small slit was left.

The pathological process has been divided into four stages (Boyko, 1940). The first stage is hardly distinguishable from atrophic rhinitis and a diagnosis is possible only by the complement-fixation reaction. In the second stage there is the formation of soft nodules of non-specific granulation tissue with predominance of plasma cells where the specific organisms are difficult to demonstrate. In the third stage the typical scleromatous infiltration makes its appearance and a typical histological picture becomes evident. The fourth stage is the stage of cicatricial contraction and deformity where the specific inflammatory tissue is replaced by fibrosis. In this series, cases 2, 3, 4 and 6 fall under stage three with the specific scleromatous deposit. In case 5 a biopsy could not be carried out. Case 1, though clinically typical, was in the stage of fibrosis where histological examination was of no value.

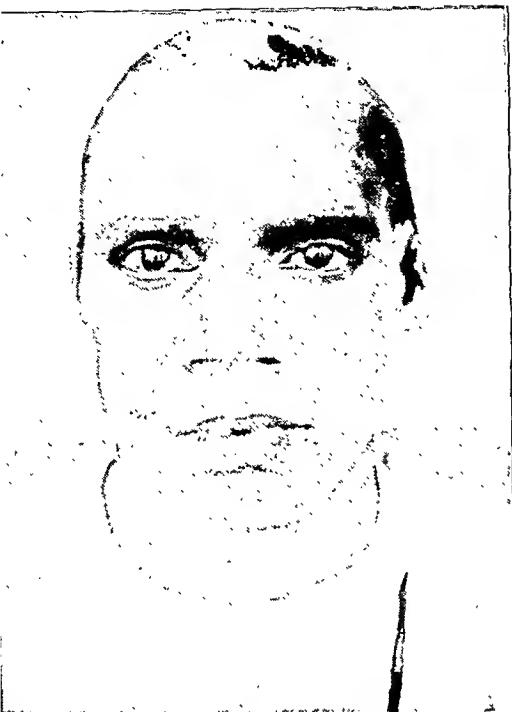

Histologically, case 2 showed a dense inflammatory granuloma under the surface epithelium. This extended deep down into the dermis involving the fibrous connective tissue so as to form a tumour-like mass of cells. Bundles of fibrous tissue walled off the growth and subdivided it into densely infiltrated cellular areas. The predominant cell type was the plasma cell with basophilic cytoplasm and cart-wheel nucleus. In places, the appearance was not unlike that of a plasma-celled tumour. A few of the plasma cells showed a faintly acidophilic cytoplasm, while others showed round acidophilic material in the form of large droplets in the cytoplasm—a degenerative change showing all the stages of the evolution of Russel's fuchsinophile bodies. The eosinophilic droplets increased in size and some fused together, so that the whole cell was converted into a large vacuole with a compressed distorted nucleus on one side. In others, the eosinophile droplets remained discrete, but increased in size, so that the whole cell resembled a cluster of grapes with an irregular nucleus in the centre. In between dense accumulations of plasma cells, there were fibroblasts and tissue histocytes with large vesicular nuclei, distinct nucleoli and prominent thin chromatin threads, an appearance not unlike that of proliferating endothelial cells. Polymorphonuclear cells were occasionally met with, especially towards the surface of the granuloma; lymphocytes and eosinophile leucocytes were few. Thick-walled young capillaries were occasionally met with, but were not so numerous as in granulation tissue. The characteristic histological feature, however, was the presence of large swollen mononuclear cells, 30 to 40μ in size, with foamy cytoplasm, or with cytoplasm almost completely absent except for a few thin strands passing from the nucleus towards the periphery. The nuclei appeared compressed and irregular, being generally central in position

and sometimes at the periphery. These characteristic Mikulicz cells were filled with clusters of the capsulated bacteria, *K. rhinoscleromatis*, which could be well demonstrated by Wiegert's fibrin stain and the Murray-Drew method. Under low magnification, the Mikulicz cells appeared like large polyhedral vegetable cells giving a characteristic vacuolated appearance to the inflammatory tissue. In between all these differing cell types, there was a groundwork of delicate collagen fibrils, scanty in places and denser in other areas. The arterioles showed no endarteritis and caseation necrosis was not met with. The surface epithelium was intact and showed slight infiltration with polymorphonuclear cells.

Case 3 showed areas of an adenomatous proliferation of the nasal mucous glands. Surrounding the gland acini, however, was an inflammatory granuloma consisting mostly of plasma cells. Here and there nodules of lymphoid tissue were also met with and polymorphonuclear infiltration was more marked. Thick-walled capillaries were more numerous. Fuchsinophile degeneration of the plasma cells and the characteristic Mikulicz cells were present showing capsulated bacteria.

Case 4 showed positive smears and culture. Here the surface epithelium was thinned out and ulcerated and the whole dermis infiltrated by the granuloma. Under the low power, the foamy vacuolated appearance of the Mikulicz cells was characteristic. The histological appearance was similar, except for a more marked fibrosis. Degenerated plasma cells showing eosinophile bodies were common. Polymorphonuclear cells were few. An examination of the smear showed the organisms inside the swollen mononuclear cells. These were typical plump rods with rounded ends, Gram-negative and capsulated, lying in clusters inside the cytoplasm. Each cluster was surrounded by a vacuole where the cytoplasm of the cell had undergone degeneration. This appears to be due to the fusion of capsular material, for with increasing intracellular multiplication the vacuoles fused together and the whole cytoplasm appeared foamy giving rise to the characteristic empty appearance of the Mikulicz cell. A remarkable feature was the increase in the size of the organisms in the later stages of invasion of the cells. Thus, the early intracellular forms were about 1 to 4μ in size, but in the later stages the bacilli were 1.5μ in length and $.6\mu$ in thickness. With rupture of the infected cells, each organism appeared larger from adhesion of the cytoplasm from the disintegrated cell. A comparison of the morphology of *K. rhinoscleromatis*, as met with in smears, with *K. granulamatis* of venereal granuloma showed that the small cocco-bacillary and typical diplo-bacillary forms of the latter (Menon and Krishnaswami, 1935) were not met with. *K. rhinoscleromatis* were distinct rod-shaped bacilli and on the whole were larger in size. The degenerative changes

PLATE XV

Case 3 showing the early stage of involvement of the alæ nasi. The skin is not ulcerated.

Case 6 on admission; the involvement of the alæ nasi and the upper lip is well marked.

Case 4 showing extensive ulceration involving the nose and the upper lip.

Case 6 showing the marked improvement with radium treatment.

PLATE XVI

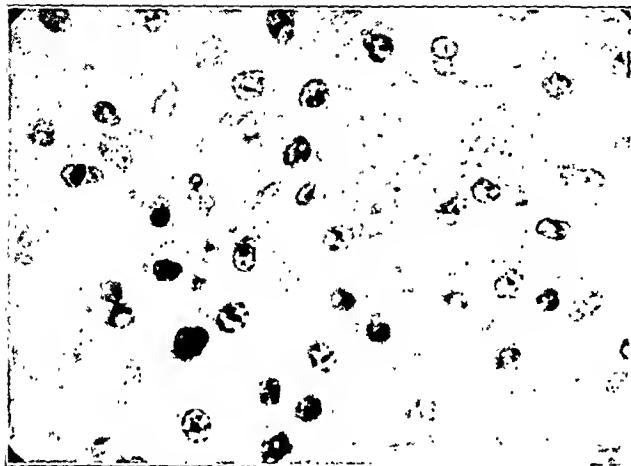

Fig. 1 showing numerous plasma cells and one large Mikulicz cell where the intracellular organisms are faintly visible (H. and E. $\times 540$).

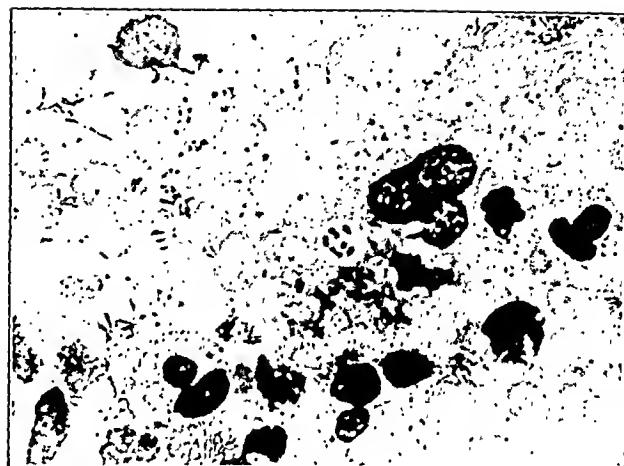

Fig. 3 showing the appearance of the early stage of *K. rhinoscleromatis* in a vacuole inside a swollen Mikulicz cell in a smear (Leishman's stain $\times 540$).

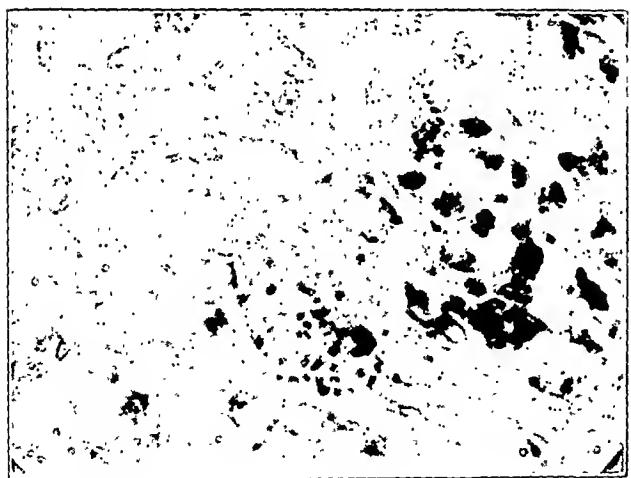

Fig. 2 showing the demonstration of the organisms inside the Mikulicz cell in a section by Weigert's Fibrin stain. $\times 540$.

Fig. 4 showing the change in the morphology of the organism after intracellular multiplication and rupture of the cell in a smear (Leishman's stain $\times 540$).

in the cytoplasm of the affected cell were more or less similar.

Comment

The six cases in this series came from the Oriya-speaking tracts of Vizagapatam and Ganjam, all from the rural areas, excepting case 3 from the town of Berhampore in Ganjam District. They are all from the poorer strata of society, which accords with the observations of the European writers. It cannot however be said that any of these patients come from any of the primitive tribes. It has been said that several members of a family are often affected. But there is no history of any infection in the other members of the family in any of the cases in this series. Cases 2 to 6 present appearances which warrant their being brought under stage 3. Though case 5 left the hospital before a biopsy could be done, the gross clinical picture was very characteristic. Case 1 was the first to be diagnosed clinically as a case of rhinoscleroma. But repeated pathological examinations of the specimen did not confirm the clinical diagnosis, possibly because the condition had already reached the fourth stage of its progress.

With regard to symptomatology, the disease gives rise to a slow gradual and increasing obstruction to breathing and catarrh of the nose. While painless throughout, there may be some tenderness on pressure. The obstruction to breathing may become complete. When the larynx is involved there is cough, hoarseness, expectoration of crusts followed by dyspnoea, stridor and eventual stenosis. The trachea and bronchi are rarely affected. In all the six cases of this series, obstruction to breathing through the nose was more or less complete. In none of these was the glottis involved. In case 1 the fauces was reduced to such a small chink and the nasopharynx was so completely shut off by a diaphragm that there was difficulty in breathing that necessitated a tracheotomy. He was able to swallow only liquids. No characteristic smell as has been described by others was noticed in any of these cases. It is possible that the smell disappears in the later stages of the disease to which all these six cases belong. The long history, slow progress, absence of pain, stony hardness of the tissue, the dry secretion, absence of ulceration or destruction of bone, and other clinical appearances left no doubt as to the diagnosis.

With regard to prognosis, though the recorded cases in the literature show no cure by any method of treatment at our command, it has been noticed that the prognosis is good as regards general health unless marked stenosis interferes with respiration or deglutition. The six patients in this series were in fairly good health, including even case 1, in spite of his being forced to live only on liquid diet.

With regard to the method of treatment, satisfactory results have been reported only by treatment with roentgen rays or radium bromide

(Robinson, 1930; Mathers, 1935). In cases 1 and 2, radium implantation did not effect any improvement. In case 3 radium mould gave some relief. The anterior nares were dilated by means of rubber tubes. In case 4 radium (230 mg. hours) did not have any apparent effect on the condition. A course of urea-stibamine injections produced considerable improvement. In case 6 a course of fouadin and neutral iodine were successively tried, but there was no improvement, however a final trial with radium gave very satisfactory results. The local condition was completely relieved. The anterior nares were dilated and the dilatation was kept up by keeping rubber tubes inside. At the time of discharge from the hospital the patient was able to breathe freely through the nose. The nasopharyngeal space was more roomy and the soft palate less dense and moving more freely. In case 1 in whom the Wassermann was positive, a course of N.A.B. injections was given with no apparent beneficial effect on the local condition.

Summary and conclusion

1. Case reports of a series of six cases of rhinoscleroma coming from the Oriya-speaking tract of Ganjam and Vizagapatam who have been admitted to the K. G. Hospital, are presented.
2. The diagnosis was confirmed in all but two by histological evidence.
3. The improvement in the local condition by radium treatment has been demonstrated specially in case 6. A course of urea-stibamine in case 3 effected some improvement in the local condition.
4. The characteristic histological changes in the disease are also brought out; changes in the morphology of *K. rhinoscleromatis* are emphasized.

SOME OBSERVATIONS ON ENTERIC FEVERS

By WAMAN D. SULAKHE, M.B. (Bom.),
M.R.C.P. (Lond.), F.R.F.P.S. (Glas.)

FROM Bombay Presidency about 5,000 to 8,000 cases of enteric fever are reported every year and Bombay city accounts for more than 2,000 cases out of them. There were two widespread epidemics here, one in 1937 and another in 1938. It is quite probable that actual incidence is much more than reported. Among the obscure types of pyrexia that are commonly met with in a general hospital in this country, the enteric group will probably account for the majority. So I propose to submit some observations on enteric fevers along with a study of 75 consecutive case-records of the disease admitted and treated in Sir J. J. Hospital, Bombay, during 1939-40, with the object of bringing to notice some of the atypical features of clinical and prognostic significance.

In the medical literature there are so many contradictory statements about the prevalence of enteric in the tropics. Manson-Bahr (1931) thinks typhoid to be the scourge of the young European in India and he ascribes the immunity of native races to typhoid as probably due either to mild attacks in childhood or to the immunizing effect of constant contact with the infection. While Lakin (1937) thinks that paratyphoid A is prominent in India, Minchin (1939) from Madras found only 2 cases of paratyphoid A and one case of paratyphoid B among 444 cases of enteric fever. Yodh reporting on 60 consecutive cases from a hospital in 1937 stated that in the present years, *B. typhosus* was the causative organism in most of the cases.

Even in temperate climates and in most of the countries with good sanitary conditions and a high standard of living, enteric fevers are endemic with occasional outbreaks of epidemic prevalence.

Season.—Cases generally occur at all times of the year. The maximum incidence in this series was shown in June, July and August.

Age.—Enteric is considered as a disease of early life—being fairly common in the first decade of life though rare in infants. This series only includes individuals above 14 years of age and the incidence was most frequent in the third decade of life with a progressive fall after 30 years, as will be seen from the following table :—

10-20 years	20-30 years	30-40 years	40-50 years	50-60 years	60-70 years
19	26	19	7	3	1

Sex.—Males are attacked more frequently than females. In this series there were 67 males and 6 females.

Community.—The cases came from all communities and comparatively no single community was favoured with high incidence. This series includes no Europeans because most of them are treated in the European General Hospital.

Pathogenesis.—The enteric fevers are due to infection by *B. typhosus* and *B. paratyphosus* A, B, and C. The bacillus reaches the blood stream through the intestinal lymphatics and thoracic duct, thereafter it is localized to the reticulo-endothelial system in liver and spleen. From the liver it is transferred to the gall-bladder which carries it with its bile to the intestine to cause the pathognomonic typhoid ulceration in the intestines.

Modes of onset

The usual classical onset is insidious, coming on slowly with malaise, frontal headache, insomnia, pains in the back and limbs and constipation or diarrhoea. There may be feeling of chilliness but hardly enough shivering to be called a rigor. Some cases do get epistaxis at the onset and there may be cough, dry in character. Along with these there is slight rise in temperature which does not come to normal for a week or so. The temperature progresses in a step-ladder-like gradation with evening rises and morning remissions. The pulse is usually slow and there is leucopenia. The tongue is covered with fur in the centre and the margins are clean and red. From the review of these 75 cases one is inclined to suggest that the most frequent mode of onset and certain symptomatic features are getting less common than before, as will be indicated in the following analysis.

The insidious type was found in 70 per cent (53 cases), the commonest symptoms being continuous fever, headache, backache and constipation or diarrhoea.

In 10 per cent (8 cases) the fever started with a definite rigor. The temperature maintained that intermittent character for 3 to 4 days after admission to the hospital, and thereafter assumed the continuous type. These cases gave rise to confusion in diagnosis, the blood films being negative to malarial parasites on examination. All these cases were admitted to the hospital earlier than other cases and got the advantage of hospital care which is so essential in this malady.

In 8 per cent (6 cases) there were patches of broncho-pneumonia consolidation in one or both lungs—there was dyspnoea and the respirations were hurried, but, along with these, there was distension of the abdomen with gurgling in the right iliac fossa and in some cases splenic enlargement, these features pointing to the necessity of further investigation to come to proper diagnosis.

Only one case came with lobar type of consolidation; this so-called 'pneumo-typhoid' type was rare. This agrees with the same infrequency stressed by Yodh (1937).

In 6 per cent (5 cases) the patients on admission were apathetic, semi-conscious, stuporose and suffered from low-muttering delirium. Some of these cases showed signs of meningism but on investigation with lumbar puncture no definite cytological or bacteriological evidence of meningitis was found. These were the cases who came to the hospital in the third week of the disease, being extremely toxæmic and difficult to treat.

Only one case came with jaundice as the presenting symptom, the jaundice being of the toxic-infective variety. The case proved fatal within 14 days. Jaundice occurring at the onset of enteric fever is very rarely mentioned in the literature but it is stated that jaundice of the toxic variety is not at all uncommon in private practice, in the proved cases of enteric fever. Jaundice occurring as a complication during the second or third week is quite conceivable, but its occurrence at the onset is rare; it seems therefore worth while making a note of it.

Another case came with flitting joint pains, excessive sweating and high fever; after 2 days of salicylate therapy without response, the temperature chart showed a continuous type of curve and the Widal reaction was positive (*B. typhosus*).

SYMPOTMS

Constipation is a fairly common symptom in enteric fever; it was present in 60 per cent of the cases of this series.

Diarrhoea at the onset is less common than constipation but a certain number of cases get this troublesome complication at the beginning of the second week. The cases coming as late as the 14th day come with diarrhoea and continuous pyrexia. Firstly, one has to exclude bacillary dysentery, and, secondly, this type proves refractory to all sorts of treatment by correction and limitation of the diet, large doses of bismuth orally, and opium in the form of starch and opium enemata. Diarrhoea is very exhausting to the enteric patient and these cases are likely ultimately to succumb from exhaustion or complications like haemorrhage and perforation. In this particular series diarrhoea as a presenting symptom was present in 16 per cent of the cases (12), and out of these 5 proved fatal.

Cough is recognized nowadays to be a common accompaniment of enteric fever and there are found bronchitic signs in the lungs—cough was present in 80 per cent of the cases in this series (60 cases).

Epistaxis is mentioned in the textbooks as one of the common symptoms at the onset of enteric. Five per cent (4 cases) in this series gave a history of epistaxis before admission to the hospital. One case had recurrent epistaxis while in the ward.

Tongue—the typical 'typhoid tongue' with red clean margins and fur in the centre was observed in the majority (60 cases).

Pulse—slow pulse rate and its dicrotic character is often a differentiating point in favour of enteric fever as against some other acute infections, and is likely to prove fallacious in a certain number of cases. Thus, the pulse rate in more than 50 per cent (40 cases) in this series was 100 to 120 per minute. So slow pulse was uncommon in this hospital-class of patient; it must be mentioned that most of the cases came to the hospital after the first week.

Rash—the 'rose spots' are extremely uncommon in this country and on account of the dark complexion of the people it is very difficult to detect them. The rash was only mentioned in one case and that was very sparse, about 6 to 8 spots on the abdomen.

Spleen—was palpable in 25 per cent (20 cases); it was soft in consistency and tender on palpation.

DIAGNOSIS

Leucopenia is a constant feature of typical typhoid and is stated to be constantly present in uncomplicated cases. In this series of 75 cases, the white blood corpuscular count was done in 59 cases. It ranged from 3,000 to 18,000 per c.mm. It was below 5,000 in 24 per cent (18 cases) and was between 5,000 to 7,000 in 17 per cent (13 cases), and above 7,000 in 37 per cent (28 cases). So it will be noted that leucopenia, so constant a feature, was present only in less than half of the cases in this series.

Blood culture.—If the blood is taken during the first week, it is positive in most of the cases. The bacteræmia though transitory occurs intermittently and the blood culture is quite likely to become positive during the second or third week of the disease. In this series because most of the cases came late the blood culture was attempted only in 4 cases and in all those it was reported sterile.

Clot culture has proved of great value in the early diagnosis and has shown the causal organism in a fair proportion of cases before the agglutination reaction becomes positive (Soman, 1932; 1934). It was attempted in 21 cases and in 2 cases *B. typhosus* was isolated.

Widal reaction.—Agglutinins are generally developed in the blood 7 to 10 days after the infection. In some cases they do not develop until 6 weeks or may not appear at all throughout the disease. So the agglutination test may be positive in the first week and it is usually so in the second week. So a negative result in the first fortnight means little or nothing; if it continues to be negative after the third week, we may be required to revise our diagnosis. If the reaction is positive, it means that the patient either has enteric fever at the moment or has had it previously. Previous prophylactic inoculation gives rise to further difficulty. If the test is repeated and found positive in rising titre, it suggests active

infection. It is found that the inoculated person gives rise more commonly to 'H' type of agglutinins than 'O' type. 'O' titre 1 in 100 is taken as diagnostic and rising 'O' titre is still more confirmatory.

In this particular series the reaction was done in all except 5 cases where they came with complications and died within 48 hours after admission. Out of 70 cases, 25 cases (36 per cent) were reported negative repeatedly to *B. typhosus* and *B. paratyphosus* A and B. In 45 cases (64 per cent) it was positive in diagnostic dilution (1 in 100) on repeated observation, in 3 cases the reaction was positive to *B. paratyphosus* A and B in addition to *B. typhosus*. None of these cases offered any history of previous prophylactic inoculation. Only one case gave definite positive reaction to *B. paratyphosus* only. In 2 cases the patients gave a history of previous attack of typhoid, one case had a definite second attack with an interval of a month and a half. The case was treated and investigated under the same physician and was undoubtedly a case of recurrent attack. It is interesting because it is well recognized that one attack confers life-long immunity. Similar instances of two or three attacks of typhoid are mentioned in the literature (Box, 1937; Lakin, 1937). Bacteriologically all cases except one in this series were due to infection by *B. typhosus*. This finding in this series along with the results from Madras (Minchin, 1939) throws doubt on the statement that paratyphoid A infections are prominent in India.

COMPLICATIONS

Hæmorrhage.—This serious complication generally occurs at the end of second week when separation of sloughs begins. The incidence of this complication has been variously stated to occur in 3 to 8 per cent of the cases. In this series, this complication occurred in 3 of the cases (4 per cent); the amount of blood passed varied from a few ounces to large tarry stools. The hæmorrhage was brought under control by stopping all intake by mouth except normal saline, by repeated starch and opium enemata and by parenteral administration of calcium and hæmoplastic sera. But these patients had diarrhoea in addition and came very late in the course of the disease, as will be seen from the following table:—

Number	Duration of pyrexia before admission	Stay in hospital	
1	20 days	8 days	Died.
2	21 "	19 "	"
3	14 "	6 "	"

In all these 3 cases the diet was mainly liquid consisting of milk, buttermilk, whey, fruit juice, weak tea or coffee and arrowroot or

sago congee. In addition, the patients had glucose along with the feeds and by intravenous route. The total calories amounted approximately to 1,500 to 2,000 per day.

Perforation.—This most dreaded of the complications is fortunately rare. The incidence is stated to be 3 to 4 per cent. The fatality rate even after prompt surgical treatment is high and so its treatment remains chiefly preventive. In this series 2 cases came during the third week of the disease with definite evidence of perforative peritonitis, tenderness, board-like rigidity and obliteration of liver dullness. In one case there was localized suppuration in the peritoneum. This patient was operated upon soon after admission and perforation was found in the ascending colon. The second patient died before operation was resorted to.

Pneumonic conditions.—During the third week and subsequently, pneumonic conditions are fairly common. They may take any of the various forms such as hypostatic congestion, pneumonitis, broncho-pneumonia or lobar consolidation. These conditions occurred in 9 cases (12 per cent) in this series. It is apt to occur in those who were debilitated by age or previous disease. Of the 9 patients, 5 recovered and 4 died.

Parotitis.—This is due to ascending infection through the parotid duct. The hospital patients are apt to get it less frequently than those who are treated at home. Signs of inflammation of the parotid were recorded in 5 cases (6 per cent). All subsided after fomentations and with oral hygiene, except one where incision and drainage was necessary.

Relapses.—Relapse is a peculiar phenomenon very common in enteric fever. It is the repetition of the original fever, usually of a shorter duration and in a milder form. Relapses occurred in 4 cases (5 per cent), of these 3 had only one and one had two relapses. The interval was from 4 to 10 days and all the cases with relapses recovered.

The other complications that occurred were pyelitis in 4 cases, hyperpyrexia in 2 cases, chole cystitis in one, persistent hiccup in one, osteomyelitis of the tibia in one, and encephalitic syndrome in one. As sequelæ deafness and sacro-iliac arthritis were observed in one case each.

Duration.—Most of the cases came late in the course of the disease to the hospital. The duration of pyrexia before admission to the hospital ranged from 2 to 50 days, and the mean average was 10 days in this series.

The average duration of pyrexia after admission was 22 days and the average stay in the hospital about 30 days.

Mortality.—Even in England the death rate in enteric is stated to be from 15 to 20 per cent where the patients are in hospital quite early. In this series 19 patients out of 75 died. The

BRUCELLA INFECTION IN VIZAGA-PATAM

By N. G. PANDALAI, M.D., D.T.M. (Cal.), M.R.C.P. (Ed.)
and

T. K. RAMAN, M.D., D.T.M. (Cal.)

(Andhra Medical College and K. G. Hospital,
Vizagapatam)

BRUCELLA infection in man is present in some parts of India, especially the north-western region. Sporadic cases have been reported from several other parts; no definite case backed up by bacteriological or serological evidence has been so far reported from Vizagapatam.

Suspected cases of Brucella infection come under observation every year in the King George Hospital. During a period of 6 years ending 1939, the specific organism has been isolated from three cases and a high titre of agglutinins obtained in three others. Only those cases in which the sera gave agglutination reaction of 1 in 640 or more are included in this.

(Continued from previous page)

death rate was thus 25 per cent. Of the deaths, 9 were due to various complications and 10 died of toxæmia with cardiac failure.

SUMMARY

Seventy-five case-records of enteric fever are examined and studied with a view to stressing the frequency of atypical clinical features. The majority of the cases were due to infection by *B. typhosus*. Maximum incidence was found in the months of June, July and August. The cases with diarrhoea at the onset showed a higher mortality than those with constipation. Slow pulse was an uncommon feature. Leucopenia was present only in less than half of the cases. Widal reaction was positive only in 64 per cent of the cases in diagnostic dilution on repeated observation. The death rate was 25 per cent.

Acknowledgments.—I am grateful to Lieut.-Colonel S. L. Bhatia, M.D., F.R.C.P., I.M.S., for permission to study these case-records and report them, and for many helpful suggestions.

I am also thankful to Dr. B. B. Yodh, M.R.C.P., and Dr. R. V. Sathe, M.D., M.R.C.P., for their kind help in preparing this paper.

Typical clinical pictures were present in all these cases.

In all the six cases cultures were done with the patients' blood as well as urine. Blood culture was done as early as possible during the ascending period of a febrile bout. The time of taking blood was in the early afternoon just before the temperature had reached its acme. Two flasks containing 100 c.c.m. of glucose broth in each were used for one blood culture and the quantity of blood inoculated into each was five cubic centimetres. One of the flasks was incubated aerobically and the other in an atmosphere of 10 per cent CO₂ tension. The cultures were not declared negative and discarded before the tenth day. In each case three such examinations were done on three consecutive days. The same procedure was followed in culturing urine, except that the time of culture was during the descending period of the febrile wave and the amount of inoculum was 20 c.c.m. Early morning specimens drawn with aseptic precautions were chosen for the purpose. The medium used for subcultures was glucose agar. When a morphologically-suspicious organism was isolated its biochemical and metabolic characters were studied, but the identification was entirely based on the results of agglutination test with the specific serum (Burroughs Wellcome anti-melitensis serum). For this purpose, immediately the strain was isolated, suspensions of growth from solid media were made in 0.5 per cent phenol in normal saline and kept in the incubator for 24 hours. It was standardized to match the opacity tube containing 1,000 million *Bact. coli* per c.c.m. (Topley and Wilson, 1936). This formed the antigen. The question of rough variants vitiating the result was kept in mind; so also the phenomenon of prozone.

Antigen for agglutination test with the patients' serum was also prepared in the above-mentioned way; two strains of melitensis and two strains of abortus were included in each. Care was taken to use only smooth strains. In the preparation of stock antigen in this laboratory, it is not usual to employ heat. Concentrated antigen was prepared and preserved in the refrigerator, and suitably diluted just before use.

A modified Dreyer is the routine method of agglutination test adopted in this laboratory. The maximum dilutions employed in the test against Brucella organisms were 1 in 5,120. After the addition of antigen the racks were put in the water bath at 55°C. for 2 hours and the results were finally read the following morning.

The results of these tests together with short clinical descriptions of the cases are given below:

Cases in which Br. melitensis has been isolated

Case 1.—Hindu female, 13 years old, was admitted with a history of long-continued fever. Examination

for enteric, malaria, tuberculosis, etc., proved negative. The third blood culture turned out to be positive for *Br. melitensis*. The organism was also isolated later from her urine. Minute enquiry into the history elicited the fact that she had been taking goat's milk.

Case 2.—Hindu male, aged 22 years, butcher by trade, was admitted on 13th December, 1938, with a history of continuous fever of fifteen days' duration. Physical examination showed an enlarged spleen, slow pulse and leucopænia simulating typhoid fever. Widal reaction was positive in low titre for *Bact. typhosum*—1 in 80 (H). The temperature gradually came down to normal on 23rd December, but began to rise again. Taking it to be a relapse of typhoid fever, the Widal reaction was repeated on 26th December, when no rise in the titre was observed. From 31st December the temperature started swinging, but no significant change in the Widal reaction was forthcoming. However, the patient began to complain of pain in the joints and marked sweating every day. The provisional diagnosis was revised to undulant fever. Agglutination test on 10th January, 1939, gave a positive reaction for *Br. melitensis*, the titre being 1 : 1,280.

After touching normal a second time, the temperature started again, the third wave. Examination of blood showed 5,000,000 red cells, 6,250 leucocytes, and 70 per cent haemoglobin. Blood agglutination on 25th January was positive for *Br. melitensis* at 1 : 5,120 and for *Br. abortus* at 1 : 1,280. Repeated blood cultures proved negative, but the fourth urine culture, on 26th January, was positive for *Br. melitensis*. The same organism was isolated from the urine drawn also on the following day. A persistent positive agglutination reaction in low titre against typhoid H antigen was an interesting feature of this case. He had no history of typhoid. He was given two injections of solu-septisine, followed on the next two days by prontosil tabloids by mouth. The temperature came to normal on 31st January, and he was discharged cured on 6th February. Nothing significant was reported on subsequent enquiries.

Case 3.—Hindu male, aged 50 years, a butcher by trade, was admitted on 20th October, 1938, with a history of irregular fever of one month's duration. An enlarged liver and spleen were the only positive findings on physical examination. Blood smear was normal. Urine showed traces of albumin, few pus cells and occasional red cells. Blood culture was negative, but the serum reaction gave a positive result for paratyphoid A (H) in 1 in 640. The temperature touched normal on 16th November, and the patient was discharged next day.

On finding out that he was the father of the previous patient, we re-admitted him on 14th February, 1939, for further investigation. His liver was more markedly enlarged this time. Blood examination showed 5,000,000 red cells, 6,000 leucocytes—neutrophils 53 per cent, lymphocytes 29 per cent, mononuclears 4 per cent, eosinophiles 9 per cent, metamyelocytes 5 per cent and 90 per cent haemoglobin. *Br. melitensis* antigen was agglutinated by his serum at 1 : 1,280 and *Br. abortus* at 1 : 160 and *Br. melitensis* was isolated from his urine. He was discharged on 18th February.

He was admitted a third time on 20th April, 1939, with a relapse. The temperature was irregular. Curiously enough the blood showed this time a high content of agglutinins against *Br. abortus*—1 in 5,120—but practically none against *Br. melitensis*. The patient was treated with hexamine by mouth and liver extract injections. The fever came down and he was discharged on 3rd June.

He was readmitted, for the fourth time, on 2nd July, as an emergency case for haematemesis. The temperature varied between 99° and 102°F. and he had four profuse bleedings in the ward. Gastric analysis, carried out after the acute symptoms subsided, revealed a normal curve. Albucid was given by mouth, 44 tablets in the course of ten days. He was free from symptoms and discharged on 23rd July. On 22nd

July, his blood agglutination was 1 in 2,560 against *Br. melitensis* and 1 in 1,280 against *Br. abortus*. This time attempts to cultivate the organism did not succeed.

Follow up shows that the patient is well.

Serologically positive cases.—In these, attempts to isolate the organism were unsuccessful.

Case 4.—Hindu male, aged 38 years, was admitted on 11th March, 1938, with a history of fever and pain in the right hypochondriac region of six days' duration. The only positive finding on physical examination was a slightly enlarged liver. After remaining continuous for the first few days, the temperature assumed an intermittent character with an occasional double rise. Examination of blood showed 4,000,000 red cells, and 6,400 leucocytes—polymorphonuclears 66 per cent, lymphocytes 30 per cent, mononuclears 1 per cent, eosinophiles 3 per cent; a few pigmented mononuclears were noticed. He had bleeding from the bowels twice. All diagnostic procedures were negative. Quinine and hexamine were administered with no effect. Liver puncture was done for Leishman-Donovan bodies with a negative result. He was given urea stibamine empirically but it had no effect. Agglutination test showed 1 in 640 (not end) for *Br. melitensis* on 22nd April. At his own request the patient was discharged on 25th April, with the temperature continuing.

He was readmitted on 23rd July with the same complaint as before. The enlargement of the liver was greater, 3½ inches below the costal margin and painful. He was put on a full course of emetine injections. The temperature came down but the enlargement of the liver persisted. He was discharged on 4th August.

Three months later he came to the out-patient department with arthritis of the left hip joint and was referred to the surgical side. His liver was still enlarged. In view of the presence of Brucella infection in Vizagapatam, his blood was again examined on 18th January, 1939, and gave a positive result of 1 in 2,560 for *Br. melitensis* and 1 in 640 for *Br. abortus*. This was a case of undulant fever, first undiagnosed and later diagnosed as amoebic hepatitis because of the enlarged liver without any enlargement of the spleen, and finally as *Br. melitensis* infection based on the result of the agglutination test. He had arthritis of the left hip as a complication.

Case 5.—Hindu male, aged 42 years, was admitted on 24th January, 1939, with a history of fever of two months' duration. Nothing abnormal was revealed on physical examination. The temperature was first continuous but later became intermittent. Blood picture was 4,500,000 red cells, and 3,600 leucocytes—polymorphonuclears 45 per cent, lymphocytes 44 per cent, mononuclears 2 per cent, eosinophiles 9 per cent. Repeated culture of blood and urine yielded no positive results but agglutination test with serum gave the following results: 25th January, positive for melitensis at 1 in 2,560 and abortus at 1 in 1,280; on 10th February, both 1 in 1,280. The patient was discharged cured. Agglutination test was done about ten months later (21st November, 1939), when it was 1 in 320 against *Br. melitensis* and 1 in 160 against *Br. abortus*. Subsequent tests showed a falling titre.

Case 6.—Hindu male, 60 years old, was admitted on 9th December, 1939, with a history of fever and pain in the joints of four days' duration. He is a wandering destitute usually living at Vizagapatam. He went to Khargpur from here and four days later he got fever and returned immediately to Vizagapatam and was admitted to this hospital. Physical examination did not reveal anything abnormal except a slightly palpable spleen. Temperature ranged between 99° and 103°F. and came down to normal at the end of ten days. After three days it rose again, became intermittent, and finally touched normal on 4th January, 1940. Blood and urine culture were unsuccessful; agglutination test was positive for *Br. melitensis* at 1 in 5,160 (not end) and for *Br. abortus* at 1 : 320.

Discussion.—The second case was diagnosed clinically as undulant fever and it was confirmed first by agglutination test and later by the isolation of *Br. melitensis* from the urine. This case led to the diagnosis of the third case, who is the father of the second case. The fourth case was first undiagnosed, but after the discovery of the presence of Brucella infection in this locality, he was traced and reinvestigated. He was proved to be serologically positive. The other two cases were clinically suspected and serologically confirmed.

The first four cases were from Vizagapatam, the fifth from Anakapalli and the last a wandering mendicant. Cases 2 and 3 are professional butchers of sheep and goats and the source of infection was clear, but in the others it was uncertain.

Two cases, cases 3 and 4, showed enlargement of the liver, and it was so prominent in both that amoebic hepatitis was suspected. Haematemesis in case 3 and bleeding per rectum in the fourth case showed the haemorrhagic tendency in this disease. The temperature in case 3 continued for nine months and albucid apparently cured the condition. Possibly it was only a coincidence.

A preliminary investigation of the prevalence of Brucella infection in animals was started and a few specimens of blood were investigated. Meanwhile the veterinary department took up the question.

The only positive proof is the isolation of the organism. In clinically suspected cases a positive agglutination reaction in a high dilution, 1 in 640 or more, will help. This receives confirmation if the titre remains high or goes higher on repeating the test.

The last three cases are likely to be due to *Br. melitensis* and not *Br. abortus* as in them the agglutinin titre was considerably and persistently higher for melitensis than for abortus, although this is not a hundred per cent proof. It was noticed during these studies that the serum from certain types of pulmonary tuberculosis agglutinated Brucella antigen in low titre. It should also be remembered that the serum of apparently normal persons may agglutinate Brucella antigen up to a dilution of 1 in 100.

SUMMARY

1. Six cases of undulant fever were discovered in Vizagapatam.
2. *Br. melitensis* was isolated from three of the cases; the other three showed a high agglutinin titre against this organism.
3. Two cases occurred in butchers dealing with goats and sheep. In other cases the source of infection could not be traced.

NOTES ON AN EPIDEMIC OF INFLUENZA

By W. LAURIE
CAPTAIN, I.M.S.

In late December 1940 an epidemic of influenza began in a camp on the N. W. Frontier of India. As this epidemic showed some interesting features it is proposed to give a report.

In view of the loose way in which the term influenza has been used, and in view of the fact that it was not possible to carry out the measures for diagnosis suggested in the *Medical Research Council Special Report No. 228* of 1938, I will begin these notes with a summary of the grounds on which my diagnosis was made.

On the 29th December, 1940, the sick parades of the units in the camp began rapidly to increase in number; the cause of the increase in the sick was almost wholly due to a condition which in the early stages showed signs and symptoms remarkably similar to those of sandfly fever, with the patients prostrated out of all proportion to the clinical findings. It was also observed that in addition to the patients who were so ill as to report on the sick parades, a large number of all ranks in the camp were complaining of 'severe colds'. The onset of the illness in all patients was very sudden, and sometimes remarkably severe as in the patient who died in the ambulance on his way to hospital from his lines, which were only five hundred yards from the medical inspection room. In the average patient, prostration of a greater or lesser degree was common, with fever, headache, and dulling of mental acuity, together with other signs and symptoms which varied according to the form of the disease; the large majority of the patients suffered from respiratory complications, this respiratory form of the disease accounting for over ninety per cent of all admissions to hospital during the epidemic; five patients of this group died. A small number of patients showed signs of the gastro-intestinal and nervous forms of the disease. Jaundice was a striking feature of those patients with gastro-intestinal complications.

On the above findings, and on the fact that I had not seen anything similar during two previous cold weathers in the camp, I decided that the epidemic was one of influenza. Subsequent post-mortem examinations confirmed the diagnosis.

The route along which the infection reached this camp also appears to have been traced. The

camp (Razmak), practically speaking, is a terminus of the road, and movements into the camp are almost wholly military personnel with a small number of civilians; all these people come usually from the plains of India. The local people are not friendly, and movement of them into the camp is very limited; on account of the local political situation, for about four weeks prior to the beginning of the epidemic there had been very few arrivals from the plains, and practically no movement into the camp of the local population. Four days previous to the sudden rise in the illness of the camp personnel, however, an influx into Razmak of large reinforcements of troops from the Punjab and from the N. W. Frontier Province began, and it seems probable that these fresh troops brought the epidemic illness with them from the plains. There had been no epidemics locally.

It is therefore suggested that the illness was influenza and that it was brought from India.

Below is given the history of two of the patients; these histories may be taken as typical of the course followed by this disease in its attack on the respiratory system during this epidemic. These case-histories have been chosen also because they give details of a central nervous system complication, which was found with these patients.

Case-history no. 1.—Gurkha Rifleman, *al.* 22 years, five years' service. This patient was admitted on the 3rd January, 1941, complaining of fever and malaria-like rigors of two days' duration; he also complained of headache and of pain over the splenic area.

Previous history.—Malaria (benign tertian), 1934.

On admission the patient showed temperature of 100°F. with pulse rate of 100 per minute, and with 26 respirations per minute.

Patient did not appear seriously ill on admission; there was no prostration. The only abnormalities detected on clinical examination were tenderness of the spleen, two-finger enlargement of the spleen, and tenderness over the appendix area. Splenic puncture showed no trace of Leishman-Donovan bodies. The only abnormality in the stools was the finding of ova of *Ascaris lumbricoides*.

The respiratory system showed no abnormality.

The blood pressure was 120/80, with haemoglobin 90 per cent, with the red cell count 4,600,000, with the white cells 6,000, and with the differential count showing polymorphonuclears 64 per cent; lymphocytes 32 per cent; monocytes 3 per cent; and eosinophiles 1 per cent.

One day after the patient was admitted into hospital ring forms of *P. vivax* were found in the peripheral blood. The patient was diagnosed as suffering from benign tertian malaria, and he was given 30 grains daily of quinine bishydrochloride, with 0.3 grammes daily of atebrin. With this form of treatment the patient's temperature and pulse rate returned to normal within forty-eight hours, *i.e.*, by the 6th January, 1941.

On the 7th January the patient complained of severe generalized pain and a cough. His temperature had risen suddenly to 101°F. with a pulse rate of 100 per minute, and with 22 respirations per minute. The patient's condition appeared to have changed markedly for the worse, with severe prostration. Repeated examinations of the peripheral blood for malarial parasites were negative. The patient showed marked dulling of the mentality with congestion of the conjunctive, with severe pharyngitis and with generalized bronchitis of moderate degree. The sputum did not show any distinctive change and the patient's cough

was not troublesome. There was no cyanosis. The predominant organism in the sputum was a haemolytic streptococcus; *Hæmophilus influenzae* Pfeiffer was not isolated. Sputum was repeatedly examined for tubercle bacilli but always with negative results. Blood serum examinations against the Brucella group, against the enteric group, and against the proteus group were all negative.

The blood pressure had fallen to 100/75; the heart sounds were toxic in character. The white cell count was 8,400 with a differential leucocyte count showing polymorphonuclears 76 per cent; lymphocytes 18 per cent; monocytes 3 per cent; eosinophiles 2 per cent and mast cells 1 per cent.

The urine did not show any abnormality.

The patient was given grains 6 of quinine bishydrochloride intravenously without any effect on the signs and the symptoms. He was then diagnosed as suffering from influenza and was given symptomatic treatment.

By the next day, 8th January, the patient's condition was worse and he appeared dazed. On this day, the lungs did not show any sign of pneumonia but in view of the severe bronchitis and the danger of pneumonia, treatment by M. & B. 693 was begun. During the day, a total of ten grammes of this drug was given.

On the next day, the white cell count was 6,900 with polymorphonuclears 67 per cent; lymphocytes 26 per cent; monocytes 5 per cent; eosinophiles 1 per cent and basophiles 1 per cent. The temperature and the pulse rate had continued to rise, and at the base of the right lung there had appeared a very limited area of suppression of breath sounds; the toxæmia had increased. This worsening of the patient's condition was regarded as being due to the onset of an influenza pneumonia, and another 14 grammes of M. & B. 693 was given.

By the evening of the next day, the 10th January, the patient had received a total of 35 grammes of M. & B. 693, the white cell count had fallen to 5,600 per c.mm. with a differential count showing polymorphonuclears 64 per cent, lymphocytes 24 per cent, monocytes 8 per cent, eosinophiles 3 per cent and basophiles 1 per cent. The temperature had risen slowly but steadily, the patient's toxæmia had increased, and fine râles were detected over that area in the right lung base where the breath sounds had been suppressed. In view of the steady deterioration of the patient's condition, with the continued reduction in the white cell count, and the increase in the severity of the toxæmia M. & B. 693 was stopped on the evening of the 10th January, the fourth day of the disease.

On the morning of the 11th January the patient developed incontinence of urine; when questioned as to why he had passed urine in bed he said that it came without his knowing anything about it. The only other abnormalities in the central nervous system were depression of the superficial reflexes and dulling of the mentality. This dulling was not sufficiently severe to prevent the patient realizing and becoming very worried about his incontinence. A lumbar puncture was done, and the fluid was found not to be under increased pressure nor was there any abnormality of the fluid.

On the 11th January the temperature began to fall, and by the 13th January it had reached normal. The urine did not contain any abnormal constituent, the cystoscope did not reveal anything abnormal, and the Wassermann reaction of the blood serum was negative.

This incontinence was not an overflow incontinence as the bladder did not at any time become distended. The urine appeared simply to run straight through the bladder as it reached it.

The incontinence of urine lasted for three days, passing off on the 14th January as quickly and as suddenly as it had developed.

The patient made an uneventful recovery and has not since had any difficulty in the control of micturition.

Case-history no. 2.—Maharatta Havildar, *al.* 32, 12 years' service. Patient was admitted into hospital on the 5th January, 1941, with complaint of generalized aching of the body, especially the large joints, frontal

headache of severe degree, and generalized weakness of three hours' duration; the attack had come on suddenly and had been ushered in by fever and a rigor. The patient said that the rigor was not like that of an attack of malaria. He also complained of a harsh troublesome cough with pain in the left side of the chest; this pain in the chest was said to be dull in character and to be increased by coughing and by deep breathing; the pain was present over an area corresponding roughly to that of the lower lobe left lung, and was particularly marked posteriorly.

Previous history.—Patient had had four attacks of benign tertian malaria in the previous four years.

On admission the temperature was 103°F. with a pulse rate of 100 per minute and respirations 22 per minute.

As was the case with the great majority of patients admitted with this disease, this patient on admission looked very like a case of sandfly fever, with a dazed expression, disinclination to talk, with languid movements and with marked congestion of the eyes. He was markedly prostrated. He showed coryza and his whole body appeared to be tender, especially over the limbs.

The tongue showed a thick white fur and the spleen was firm and one-finger enlarged; the stools did not show any abnormality.

The heart sounds were relatively slow in rate, but very toxic in character. The blood pressure was 100/65.

Hæmoglobin was 100 per cent; red cell count was 5,000,000; the white cell count was 8,800 and the differential leucocyte count was: polymorphonuclears 76 per cent, lymphocytes 17 per cent, monocytes 5 per cent, eosinophiles 1 per cent and basophiles 1 per cent. Blood films were always negative for malarial parasites.

The patient's cough was dry and barking and very persistent; sputum was scanty and not abnormal in appearance. There was a marked degree of granular pharyngitis and laryngitis. Both lungs showed generalized bronchitis and at the base of the left lung posteriorly there was a small area of medium crepitacions below the tip of the left scapula. Pleuritic friction was not found. The predominant organism in the sputum was the pneumococcus. *Hæmophilus influenzae* Pfeiffer was not isolated, and repeated examinations for tubercle bacilli were always negative.

The urine did not show any abnormality.

In addition to the mental dullness the patient showed depression of the tendon reflexes.

The condition was diagnosed as influenza, complicated by very early broncho-pneumonia. Symptomatic treatment was ordered, together with M. & B. 693, of which 12 grammes were given on the first day of treatment.

By the next day, the 6th January, there was little change; another ten grammes of M. & B. 693 were given.

By the evening of the 7th January the patient had received a total of 30 grammes of M. & B. 693 but his lung condition had steadily worsened, with the lower lobe left lung showing changes suggestive of a patchy lobular pneumonia; he showed a septic type of temperature chart; the white cell count and the differential count had not changed to any extent. On the 8th January another 8 grammes of M. & B. 693 were given, but the patient continued to lose ground; on this day the cardiac condition was unsatisfactory, and coramine was given frequently from this date onwards until the patient died; this coramine undoubtedly was of real value and it seemed to delay the fatal issue.

By the 9th January, the toxæmia had increased very markedly, although the lung condition appeared to be smaller in extent than on the previous day. There was still no significant change in the white cell count and in the differential count. On this day administration of M. & B. 693 was stopped, a total of 40 grammes having been given without any obvious good results.

By this time the patient was very dull and disinclined to talk; the deep reflexes were no longer abnormal and the only abnormality of the nervous system other than

the dullness was that the pupils were both markedly dilated and reacted only sluggishly to light and to accommodation.

At noon on this day, the fifth day of the attack, the patient became doubly incontinent; rectal examination showed no abnormality; the urine showed no abnormality, and the Wassermann reaction of the blood serum was negative. Lumbar puncture was carried out; the cerebro-spinal fluid pressure was not increased and when examined the fluid did not show any abnormality. Blood culture was sterile and agglutination reactions against the Brucella, the enteric and the protens groups were all negative.

During the afternoon of the 9th January the patient collapsed and the temperature fell to normal, but after an injection of coramine and other measures the temperature rose again.

By the 11th January, the patient was very ill, with intense toxæmia, with no change in the lung condition from the 9th January, when it was resolving, and with the mental dullness deepening into stupor; the heart sounds had become very toxic and fast.

On the eighth day of his illness the patient died. Double incontinence had persisted from the fifth day of illness.

Post-mortem report

Summary.—Tracheitis and bronchitis. Infiltration of brain and cord by small round cells. Sub-pleural and sub-pericardial haemorrhages.

Opinion.—The post-mortem findings were not in themselves specific but they corresponded to the picture found in cases of influenza.

DISCUSSION

The first point which arises is the question of the incontinence; in one patient the incontinence was urinary and lasted only for four days, whereas in the other patient both the bladder control and the sphincter ani control were lost, and remained lost until death. No local cause was discovered by clinical examination, e.g., no abnormality on cystoscopic examination; no abnormality on rectal examination; urine showed no abnormality, cerebro-spinal fluid was not under pressure and showed no abnormal constituents, and in the nervous system the only other abnormality in addition to the incontinence was the dazed mental condition; this dazed condition was common to all the patients admitted into hospital for influenza during this epidemic. In spite of the dazed mental condition the men appreciated that they had become incontinent, and were greatly disturbed by this.

As has been pointed out by Osler (Osler and McCrae, 1930) that almost every form of disease of the nervous system may follow influenza, e.g., as long ago as 1898, at a meeting of the Bradford Medical-Chirurgical Society, Kerr (1898) demonstrated two patients in whom incontinence of urine had developed following influenza. Those influenzal lesions which are reported are usually severe and generalized, as was the case with Kerr's two patients. In such patients it is to be expected that the nervous tissue will show, at post mortem, marked and widespread damage, but in those patients who came to post mortem in this epidemic the changes in the brain and spinal cord, while showing in a mild degree the picture described by Boyd (1935), did not show

destruction to a degree sufficient to explain the incontinence on the basis of toxic damage to the spinal cord or to the more central portions of the nervous system. It is for this reason I report these two examples.

The value of the sulphonamide group.—The next point, of greater practical importance, concerns the value of the sulphonamide group of compounds in the treatment of influenza and of respiratory complications of influenza. In this epidemic eighty patients were treated by sulphonamide, M. & B. 693 being used.

Of the eighty patients suffering from respiratory complications of influenza and treated by M. & B. 693, in forty-nine patients the predominant organism in the sputum was the pneumococcus; the remaining thirty-one showed a predominance of streptococci. In no case was *H. influenzae* isolated. This prevalence of the pneumococcus was also noted by Malone (1921) who considered it to be a secondary invader and a potent cause of death in the 1919 epidemic in Bombay.

Largely as a result of research by American workers, it is now widely taught that the severe pulmonary complications of influenza are the result of invasion of weakened lungs by pneumococci, streptococci, and other nasopharyngeal organisms; for example, Price (1937) says 'it seems that many of the most serious and fatal cases (of influenza) owe their lethal character to virulent streptococci'.

In view of the proved value of the sulphonamide compounds in the treatment of non-influenza streptococcal and pneumococcal diseases of the respiratory tract, it was hoped that this group of drugs would prove equally helpful in the treatment of the respiratory complications of influenza, but if our findings in this small series be typical of the results of sulphonamide therapy in respiratory influenza, then such hopes were not fulfilled. Even although in each of the eighty patients treated by M. & B. 693 the drug was given in full doses and given very early, it did not seem to have any beneficial effect whatsoever; the two case-histories given above are examples of this failure on the part of the M. & B. 693. The results obtained suggest that the sulphonamide group of drugs appeared to have no beneficial effect on the course of the disease, nor on the spread of the lung lesions.

There are other factors to be taken into account when deciding whether or not sulphonamide preparations should be given to patients suffering from 'respiratory' influenza; one factor concerns the white cells of the patient. Influenza is associated with leucopenia, even to the stage of so depressing the patient's white cell count as to produce temporary agranulocytosis, as in the patient treated by van der Molen (1939). It follows that any drug such as sulphonamide which may depress the white cell count should be of proved value in the

treatment of the disease, otherwise the extra risk is not justified.

Another factor to be borne in mind concerns the toxic effects of sulphonamide preparations; in the majority of patients suffering from influenza, the serious complications and many of the fatal outcomes are the result not of any local damage to the body or to one of its systems, but to the generalized toxæmia which is so characteristic of this disease. This is well illustrated by the prostration in the early stages of the disease, when local lesions such as pneumonia are at too early a stage to account for the generalized toxæmia. Again, therefore, it follows that if sulphonamide is not of real value in the treatment of influenza, it should be regarded as contra-indicated in view of the additional toxic effects which it may produce in a patient whose general condition is already markedly toxæmic. While this present series is too small to serve as a basis on which to give conclusions, it seems that further research is necessary to ascertain whether in respiratory influenza the advantages to be derived from the use of the sulphonamide compounds outweigh the disadvantages mentioned above. Our results suggest that the disadvantages outweigh the advantages. It was not possible to say whether this failure of the drug was due to the fact that the combination of influenza virus plus secondary invader changes the character of the secondary invader, or whether our present teaching is wrong when it holds that the influenza virus itself is not responsible for the respiratory lesions of the disease.

The last point concerns the effects of the influenza virus upon the circulatory system. In discussing influenza the majority of workers divide the illness into different forms, e.g., the pulmonary, the gastro-intestinal, and the nervous forms. In my opinion, however, clinical findings and the findings in the post-mortem room would indicate that the basis of all the pathology of this disease is the damage done to the circulatory system by the virus, for example Muir (1932), in discussing the lung lesions of the disease, mentions haemorrhages in the lungs in influenzal pneumonia, and similarly Boyd (1935) in discussing influenzal lesions of the nervous system describes punctiform haemorrhages in the brains of patients who have died of influenza. Certainly, if the sulphonamide preparations do prove of value in the treatment of influenzal pneumonia in spite of our findings to the contrary, then this classifying of influenza into forms would be justified, in so far as it would serve as a reminder that sulphonamide should be given in the respiratory forms of the disease. In the meantime, however, this classifying of patients suffering from influenza tends to obscure the important lesion requiring treatment, namely, the damage to the circulatory system.

TREATMENT OF SCABIES AND PEDICULOSIS WITH PYRETHRUM

By D. N. ROY, M.D., B.T.M.

S. M. GHOSH, M.B.

and

SIR R. N. CHOPRA, Kt., C.I.E., M.A., M.B.,
S.C.D. (Cantab.), F.R.C.P. (Lond.)
BREVET-COLONEL, I.M.S. (Retd.)

(From the School of Tropical Medicine, Calcutta)

In view of the unhappy position in which we are placed in regard to the treatment of scabies

(Continued from previous page)

In this series coramine was found to be of value, in contradistinction to the M. & B. 693.

CONCLUSIONS

In this small epidemic of influenza it was found that the sulphonamide group of drugs appeared to have no beneficial action on the respiratory type of the disease, and unless other workers obtain more encouraging results I consider that the toxic side-effects of this group of drugs are sufficient to contraindicate the use of the drugs of this type in the treatment of this disease. I consider that the underlying lesion which is of the greatest importance is the serious damage which influenza produces on the circulatory system.

I am unable to offer any explanation for the incontinence found in the two patients whose case-histories are given above.

SUMMARY

A small epidemic of influenza is reported, in which two patients developed incontinence, one showing incontinence of urine, and the other showing double incontinence.

Respiratory complications were not benefited by the administration of M. & B. 693.

ACKNOWLEDGMENTS

My thanks are due to Lieut.-Colonel G. B. Hanna, O.B.E., I.M.S., Officer Commanding C. I.M. Hospital, Razmak, for permission to publish this paper, to Lieut.-Colonel F. Harris, M.C., A. D. H. & P., Northern Command Headquarters, for assistance in the writing of these notes, and to Major J. F. Wilson, D. A. D. P., Waziristan, for the post-mortem reports on the Mahratta Havildar.

and as scabies and pediculosis have assumed positions of considerable importance in the present conditions under which both civilians and troops are living in Great Britain, we think it worth while publishing a short account of our observations on the effect of pyrethrum on simple scabies and pediculosis or when complicated by secondary infections.

It was recognized during the last world war that conditions of pyodermia, e.g., impetigo, boils, etc., had an important relationship with scabies. The pyrexia of unknown origin in its common form of trench fever was a sequel of pediculosis, and/or scabies.

Scabies

Scabies is extremely common in this country and occurs chiefly during the winter. Textbook descriptions of this disease are seldom met with among patients attending the hospital outdoor department as by the time they seek medical relief, extensive involvement of the body has already taken place. It is not uncommon to find itch on every part of the body except the face and the head, resulting in conditions which it would be difficult for an inexperienced observer to diagnose. The secondary pyoderma is also extensive and is generally of a varied nature. Many patients find it difficult to move and are completely crippled for the time being.

A very large number of remedies have been recommended for the treatment of scabies. Of all remedies, sulphur in its various forms is generally acknowledged to be the most efficient and the rate of cure in severe types of scabies which was met with in France in the last war was 31.7 days as against 3 days for the average early case.

We have no personal experience of treatment of this disease by benzyl benzoate. We have, however, used a 10 per cent ointment of finely powdered flowers of *Pyrethrum cinerariaefolium* with vaseline not only in human scabies and pediculosis but also in mange in rabbits and dogs and the striking success we have met with in these diseases in all our clinical trials has prompted us to bring it to the notice of the medical profession with a view to its wider application.

Earlier records show that pyrethrum in the form of an ointment has been used by Sweitzer (1936) in scabies. As we have had no access to his original papers, we are unacquainted with such details as the strength of the ointment used, the types of scabies in which it was tried, etc. However, he regarded this ointment as a clean, effective and valuable remedy.

Method of application.—The freshly prepared ointment should be well rubbed on the parts of the body affected by itch, especially in the evening, and once again before retiring to bed. The itching is generally relieved within 48 hours after its application. When secondary infection has set in, it is advised that the pus should be first let out before the parts are washed with

soap and hot water. As soon as the skin is dry the ointment should be applied in a thick layer. Very marked improvement is generally noticed within 48 hours after its application even in severe types showing considerable inflammation of the affected parts. If the instructions are carefully followed patients who have been crippled on account of severe inflammation will be able to undertake their usual avocations after 3 days.

What direct effect pyrethrum has on the organisms responsible for secondary infections, it is difficult to say. It is nevertheless true that after its application the ulcers show signs of healing within a remarkably short space of time.

It is not possible for us to state the average period needed for cure. As most of our patients were treated in the out-patients' department, we were not able to keep in touch with them till they were absolutely cured and the last trace of the disease had disappeared.

Ill effects.—We have not so far come across any bad effect following its application even practically over the whole body. It also does not cause any irritation of the conjunctiva when applied on the eyelids.

Pediculosis

Lice are commonly found in this country on the hairs of the head especially in women of the lower classes and in beggars, who have generally uncleanly habits. They are also not uncommonly found on European and Anglo-Indian school girls who do not wash their hair daily. The other form of pediculosis due to *Phthirus pubis*, though not very rare, is sometimes met with among all sections of society.

The symptoms caused by their presence are merely local irritation, and complications mentioned in textbooks are rare.

In louse infestation either by *Pediculus humanus capitis* or by *Phthirus pubis*, application of pyrethrum either in the form of a pomade or a watery extract is followed by equally beneficial results. As soon as the pyrethrum comes in intimate contact with the louse, the latter becomes at once inactivated and is soon killed. The fundamental basis of treatment therefore is to lay stress on the point that whatever preparation is used, it must be well rubbed into the hairs to ensure this contact.

Pediculus humanus capitis

Method of application.—The pomade is prepared with white vaseline in 8 to 10 per cent strength and is applied once in the evening. The application is to be continued for 5 days in succession which is generally taken as the incubation period of eggs (the incubation period of eggs in Calcutta during winter months is from 7 to 10 days). It should be noted that pyrethrum has no effect on nits but post-embryonic stages are quickly acted upon by it.

The watery extract is prepared by soaking 2 oz. of coarsely powdered pyrethrum flowers in about 20 oz. of water for half an hour, and thereafter heating it in a water-bath short of boiling point for another half hour. It is particularly useful in women who have long hair, and who are unwilling to apply any greasy material to their hair. Although the watery extract is slower in its action than when pyrethrum is used with vaseline, it nevertheless contains toxic properties powerful enough to kill the post-embryonic stages of this insect.

As much of the hair as possible should be immersed in a bowl containing the extract and the rest of the hair should be treated with a sponge soaked with the fluid. The treatment must be continued once daily during the incubation period of the nits.

Phthirus pubis

In connection with the action of the ointment on the crab louse we would like to refer to two cases, both boys aged 6 years and 8 years respectively, who were admitted in the hospital for some other disease in addition to infestation of the eyelids by crab lice. At the time of their admission they had blepharitis, conjunctivitis and severe inflammation of the eyelids following the infestation. Application of the ointment on the eyelids twice a day was quickly followed by recovery in the course of 3 days.

Discussion

Castellani and Jackson (1915) stated that pyrethrum powder had a very feeble action on lice. We carried out experiments on identical lines with pyrethrum grown in Japan, Kenya and India, the pyrethrum content of various samples varying from 0.5 to 1.5 per cent and found that all insects were killed within half an hour. The ointment however acts very quickly. In fact, death may occur almost immediately after its application. The watery extract acts more slowly and it takes about 3 hours for the insects to die. When vaseline is replaced by an oil, its action is uncertain.

According to Castellani and Jackson (1915) vaseline, lard and lanoline are all efficacious in themselves. According to our observations they act mechanically by blocking the spiracles of the insects. Pyrethrum, on the other hand, has a pronounced toxic action. When simple vaseline is used, the action depends on the number of spiracles which are completely blocked. While a louse will be killed almost instantly when it is immersed in vaseline, a small quantity when applied on its dorso-lateral surface, has either no action at all or the insects are not affected for 3 to 4 hours. In the case of pyrethrum ointment the action is certain and takes place quickly.

We have intentionally left out the question of reinfection in scabies during the course of pyrethrum treatment. Reinfection may take

A NOTE ON THE TREATMENT OF
RELAPSING MALARIA

By L. EVERARD NAPIER, F.R.C.P. (Lond.)
and

R. N. CHAUDHURI, M.B. (Cal.), M.R.C.P. (Edin.),
T.D.B. (Wales)

School of Tropical Medicine, Calcutta

AFTER an ordinary course of quinine, in at least 60 per cent of cases of benign tertian malaria infection, a relapse occurs. There are some patients who persistently relapse, under conditions where the possibility of reinfection can reasonably be excluded. When such a case is encountered, one should first make sure that the drug—quinine, other cinchona alkaloid, or atebrin—is actually being taken, in the doses prescribed, and, secondly, that it is being absorbed; this can be ascertained with a reasonable degree of accuracy by testing the urine by the Tanret-Mayer test in the former two cases and by the Tropp and Weise (1933) method* in the last. If the drug is being absorbed, there is no reason why the oral route should be abandoned in favour of any other route, e.g., intravenous or intramuscular, and little will be gained by increasing the dose beyond the usual 10 grains three times a day or prolonging the

course beyond 10 days (if the cinchona alkaloids are being used, or 0.1 g. thrice daily for 7 days if atebrin is the drug).

Recently, such a patient came under our charge in the hospital. Details of the case are given below:—

The patient, a European male, aged 27 years, was admitted to the Carmichael Hospital for Tropical Diseases on the 1st October, 1940, complaining of sickness, headache, and pains in the joints and left side of chest with a temperature of 102.2°F.

The history was that he came to India in September 1939, since when he had seven attacks of malaria. During the first attack he was given quinine by mouth, as well as by six intramuscular injections. During the second attack he was treated with a course of atebrin and plasmochin. For subsequent attacks he was given quinine or atebrin with or without plasmochin, under medical supervision; he did not remember the details of doses. His last attack was in the first week of September, when he was given quinine, 30 grains a day, for 10 days.

The present illness started on the 27th September with fever and rigor, which recurred every alternate day. His spleen was enlarged one inch below the costal margin and was tender; the liver was just palpable. No other abnormality was detected. He had pain on the left side of chest which was apparently due to splenitis. Blood examination showed scanty benign tertian parasites.

On the following day, the temperature was normal, but the blood smear showed scanty trophozoites.

He was left without any specific treatment until the 5th October when he was given alkalis (sodium bicarbonate gr. 15 and sodium citrate gr. 30) followed half an hour later by a mixture containing 10 gr. of quinine, three times a day, with plasmochin 0.01 gm. twice a day for 10 days. On the 11th day (16th October) he was given an injection of sulpharsenol, 18 centigrammes, intramuscularly. Next he was given a 'tonic' mixture, with liquor arsenicalis—miv, twice a day after food, for one week. On the 23rd he was given a second injection of sulpharsenol—24 centigrammes. During this period he was getting a slight temperature of about 99°F. in the evening. The blood was therefore examined by a cultural method for malarial parasites; the result was negative. He was however given another course of quinine, gr. x, twice a day for 7 days from the 24th. Subsequently, he was completely afebrile. The second course of quinine was followed by a third injection of sulpharsenol—30 centigrammes. During this period the patient definitely felt a sense of well-being and gained 5½ pounds in weight.

He was discharged after 32 days in hospital, with a recommendation for a change of climate for a few months. He was instructed to inform us should he get another relapse.

He remained entirely free from fever for more than 6 months and gained another stone in weight.

Comment.—It was shown by Acton as early as 1919 that quinine acts on the malarial parasites best in an alkaline substratum, and the alkaline treatment of relapsing benign tertian, sometimes called Sinton's treatment, is dependent on this fact.

The addition of plasmochin in small doses to the ordinary course of quinine has been shown to reduce the relapse rate considerably (Sinton and Bird, 1928).

During the last war, on account of the shortage of quinine, the Germans used salvarsan in the treatment of malaria. In the Balkan countries, where the type of malaria is very resistant

to treatment, the combining of arsphenamine drugs with quinine has long been the practice.

In the treatment in this case, and in other similar cases, we have combined these three devices for enhancing the specific action of quinine. In our experience, any one of these measures proves more efficacious than the old practice of subjecting the unfortunate patient to a very prolonged course of quinine, or the, unfortunately, common one of resorting to intramuscular injections.

Another point which this case exemplifies is the constant slight anaemia that is associated with a latent, comparatively inactive, malarial infection in which there is little evidence of haemolysis (bilirubinaemia = 0.4 mg. per cent; reticulocytes 0.1 per cent), and the subsequent recovery of the blood picture after the anti-malarial treatment.

THE SIGNIFICANCE OF THE TAKATA-ARA REACTION IN THE DIAGNOSIS AND PROGNOSIS OF HEPATIC CIRRHOSIS

By M. NARAYANA PAI, M.B., B.S.

King Institute, Guindy, Madras

THE Takata-Ara reaction was first introduced by Takata (1925) as a laboratory test for differentiation between lobar pneumonia and broncho-pneumonia. In the same year, Takata and Ara (1925) working on spinal fluid introduced a modification of the test, affording a differentiation between the syphilitic and malaritic types of spinal fluids.

The value of this test in the diagnosis of hepatic cirrhosis was first mentioned by Staub (1929); Jezler (1929) tried this test on blood serum and found that it produced a flocculation in the great majority of cases of hepatic cirrhosis. This paper deals with its value in the diagnosis and prognosis of hepatic cirrhosis.

Material employed.—Specimens of blood serum and ascitic fluid were used for the tests. Only non-haemolysed samples of blood serum and clear samples of ascitic fluid were used. Specimens arriving late in the evening were stored in the refrigerator until next morning, when the test was performed.

Technique.—A slight modification of the method described by Ragins (1935) was employed. Briefly it was as follows:—

A series of dilutions of 1 in 2 to 1 in 256 of the blood serum or ascitic fluid was made in a set of eight tubes with 0.9 per cent sodium chloride. To 1 c.c.m. of the diluted serum or ascitic fluid, 0.25 c.c.m. of a 10 per cent solution of sodium carbonate was added and thoroughly mixed. 0.3 c.c.m. of freshly prepared Takata-Ara reagent (consisting of equal parts of 0.5 per cent solution of mercuric chloride and 0.025 per cent solution of basic fuchsin) was added to each tube and the contents well shaken.

The presence or absence of a flocculent precipitate in the tubes was noted. Three readings were taken, the first after 5 minutes, the second after $\frac{1}{2}$ to 1 hour, and the third after 24 hours. Reactions were recorded as 3 plus (strong positive), 2 plus (moderate positive) and 1 plus (weak positive) doubtful and negative according to the density of the precipitate and the rapidity with which it appeared. No reaction was considered positive unless there was a fairly well-marked precipitate in at least three of the first six dilutions.

Altogether, blood sera and ascitic fluids from 117 cases were examined. I have divided them into three groups, for convenience, as follows:—

Group I consisting of 51 cases of hepatic cirrhosis.

Group II consisting of 11 cases most of which showed evidence of derangement of liver function, but had not been diagnosed as hepatic cirrhosis.

Group III consisting of 55 cases (control), suffering from a variety of diseases not specially connected with any derangement of liver function.

Group I

This consisted of 49 cases clinically diagnosed as hepatic cirrhosis and two other cases (nos. 82 and 91), which from the clinical signs and symptoms, noted below, were highly suggestive of a condition of hepatic cirrhosis.

Case 82 was a male, aged 30 years, admitted with a history of ascites of 4 months' duration. He had been admitted into hospital a month previously for a similar complaint and had been tapped. He was tapped on 31st August, 1939. The abdomen filled up rapidly and he was tapped again on 6th September, 1939, and was discharged. The diagnosis of the case was 'ankylostomiasis and secondary anaemia'. The rapidity with which the peritoneal cavity filled up after tapping and the number of occasions on which he was tapped are highly suggestive of a condition of portal obstruction due to hepatic cirrhosis. The Takata-Ara reaction was +++.

Case 91 was a male, aged 32 years, admitted with a history of distension of the abdomen for 3 years—*cæcum medusæ* present. The spleen was enlarged 4 inches below the costal margin. The liver was not palpable. Shifting dullness and fluid thrill were present. Twenty-one pints of fluid were aspirated from the peritoneal cavity. The total protein content of the ascitic fluid was 1.3 per cent. The Takata-Ara reaction was +++.

The diagnosis was 'ascites'.

This was probably a case of hepatic cirrhosis. The results of the Takata-Ara reaction in these 51 cases are given in table I.

TABLE I
Fifty-one cases of hepatic cirrhosis

Strong positive Takata-Ara reaction ..	33 cases
Moderate positive	9 "
Weak positive	5 "
Negative	4 "

Group II

The second group consisted of 11 cases all showing evidence of liver derangement, but not diagnosed as hepatic cirrhosis. The clinical diagnosis and the results of the Takata-Ara reaction in these cases are given in table II.

TABLE II
Takata-Ara reaction

Clinical diagnosis	+++	++	+	Doubtful	Negative	Total
Ascites ..	1	1	2	4
Ascites and jaundice ..	1	1
Chronic malaria with ascites (case 20) ..	1	1
Syphilitic cirrhosis of liver	1	1
Acute yellow atrophy ..	1	1
Infantile biliary cirrhosis ..	1	..	1	2
TOTAL ..	4	1	2	1	3	11

The clinical notes of some of the cases are interesting.

Case 20 was a male, aged 20 years, admitted with a history of fever, pain in the joints and ascites. The duration of the ascites was 10 days. The duration of the other symptoms has not been clearly noted; it was probably longer. The spleen was enlarged four fingers breadth below the costal margin. The liver was just palpable. The Takata-Ara reaction was +++.

The diagnosis was 'chronic malaria with ascites'. An early cirrhosis of the liver is a possibility in this case.

Case 52 was a male (age not mentioned) admitted into the Government Headquarters Hospital at Coimbatore on 26th March, 1939, with a complaint of intense jaundice, restlessness and delirium. Two days previously patient returned from work complaining of aching pain all over the body and jaundice was noted. Since that night, he developed restlessness and delirium. The pulse ranged from 88 to 110. No diminution of liver dullness. Lungs: *nil* abnormal. Urine contained bile pigment. The motions were clay coloured. The patient was taken away by the relatives on 31st March, 1939, against medical advice. No history of having taken arsenic or other medicine. Diagnosis: 'acute yellow atrophy'. The Takata-Ara reaction was weakly positive.

Case 85 was a male, aged 29 years, admitted with ascites, oedema, jaundice and irregular fever. He had taken a purgative 4 days previously for abdominal discomfort. Subsequently he noticed swelling of the abdomen and later, of the legs. Ascites was well marked. Five pints of fluid were removed from the peritoneal cavity. The liver was palpable two fingers breadth below the costal margin and pulsating. The spleen was not palpable. The patient died in hospital, developing intense jaundice. The diagnosis was 'toxic hepatitis, acute yellow atrophy'. The Takata-Ara reaction was +++.

Case 34 was a male child, aged 3 years. It was a case of infantile biliary cirrhosis. The Takata-Ara reaction was weakly positive, both in blood as well as in the ascitic fluid on three different occasions. The blood of the mother of the child gave a negative Takata-Ara reaction.

Case 151 was a male child, aged 5 years, clinically diagnosed as biliary cirrhosis. The Takata-Ara reaction was +++.

The latter four cases, *viz.*, two cases of acute yellow atrophy and two cases of infantile biliary cirrhosis, suggest that in conditions of hepatic insufficiency also, the test is positive. The clinical notes of the other six cases in this group are not available.

*Group III**Fifty-five control cases*

This group consisted of 55 control cases suffering from a variety of diseases, not specially connected with any derangement of liver function, two were cases of Banti's disease; the

other 53 were cases whose blood specimens were received at the Institute for Kahn and Wassermann test. This included latent syphilis, chronic gonorrhœa, kala-azar, leprosy, cardiovascular diseases, tumours, nervous diseases, and so on. Of these, both cases of Banti's disease gave a negative reaction. Of the rest, 45 gave a negative reaction, one a doubtful, two a weak

positive, one a moderate positive, and four a strong positive reaction. These cases are tabulated in table III. Of the two weak positives, one (case 21) was a case of chronic kala-azar, where a certain amount of hepatic insufficiency may be expected. The other case was

disease of the heart. The positive reaction in this case was probably due to a certain amount of hepatic insufficiency as a result of chronic venous congestion. The liver was enlarged to a level of about 4 inches below the costal margin. There was ascites and oedema of the legs.

TABLE III
Forty-seven cases (two cases of Banti's disease and forty-five control cases)

diagnosed as 'tumour abdomen' but no other clinical notes were available.

The case with a moderate positive reaction (case 107) was one of chronic venous congestion of the liver, as a result of chronic valvular

of the four cases giving a strong positive reaction, there are no clinical notes available in three. The fourth (case 23) was a female, aged 25 years, with a history of purulent vaginal discharge for 3 years and a tumour at

the base of the clitoris involving also the right labia and perineum. There were enlarged inguinal and epitrochlear glands. The condition of the liver was not mentioned. No conclusions can be drawn from these four cases.

The total protein content of the sera and ascitic fluids investigated

In 17 cases this investigation was done. In six of these, the relative albumin-globulin ratio is available. In the other 11 the total protein content only is known. The results are given in table IV.

TABLE IV

Case number	Serum albumin* or total protein, per cent	Serum globulin, per cent	Percentage of globulin to total protein	Takata-Ara reaction
19	0.65*	0.50	43.5	Negative
25	0.80	"
56	0.36*	0.44	55.0	"
78	0.50*	0.15	23.1	+++
83	0.12*	0.08	40.0	++
84	1.60*	0.20	11.0	+

138	0.35	+++
141	1.70	+++
143	0.65	Negative
146	0.40	+++
147	0.70	+++

In case 19 the blood serum was examined. In the other cases the ascitic fluid was examined.

Relationship between the gel test and the Takata-Ara reaction

Hassan and Salah (1939) in a series of 600 cases found a similarity between the formol-gel test and the Takata-Ara reaction. They state, however, that the formol-gel test could be relied upon to detect sera with hyperglobulinaemia, if such sera contain 4 per cent or more of globulin, and that both tests are influenced to a certain degree by the lability of the serum proteins.

In 29 cases which gave a positive Takata-Ara reaction the gel test was done on the blood sera and ascitic fluids. The results are given in table V.

TABLE V

Takata-Ara reaction.	GEL TEST	
	Positive	Negative
Strong positive. 23 cases ..	5	18
Moderate positive. 2 "	2
Weak positive. 2 " ..	1	1
Negative. 2 "	2
TOTAL 29 cases ..	6	23

Though the number of cases in this series is small the results show that there is no definite relationship between the two tests.

The relationship between Kahn, Wassermann and Takata-Ara reactions

The three reactions were compared in 82 cases. The results are tabulated in table VI. The results show that there is no relationship between the Takata-Ara reaction, and the Kahn and Wassermann reactions. This finding is in agreement with the work of Tannenholz (1933).

An interesting case with a negative Takata-Ara reaction (case 69)

R., female, aged 24 years (with masculine features such as a fine growth of a beard and moustache), was admitted into hospital for ascites of one year's duration. Hepatic cirrhosis was suspected. The serum was examined for the Takata-Ara reaction. She was tapped thrice and the ascitic fluid was similarly examined on all three occasions, but the test remained persistently negative. Laparotomy revealed a tumour of the right ovary. On section it was found to be an arrhenoblastoma. The liver was found to be normal. There was no recurrence of ascites and all the masculine features disappeared after the removal of the tumour.

Factors involved in causing the flocculation

The Takata-Ara reaction is caused by the interaction between the mercuric chloride and the serum protein as a result of which a colloidal solution of mercuric oxide is thrown down as a flocculent precipitate. It has been stated by Takata (1925), Nicole (1929), and Jezler (1930) that it is 'the decreased stability of the serum proteins of the colloid system which makes the precipitation of the colloidal solution of mercuric oxide possible and this is due to the increase of globulin with an inversion of the albumin-globulin ratio'. According to Nicole, Takata and others (*loc. cit.*), it is the albumin which exerts a protective action, thus preventing the flocculation of the colloidal solution of mercuric oxide. In a number of cases in my series, there was no flocculation in the tubes containing the first and second dilutions. In many cases a flocculation occurred in these tubes at the time of making the test but redissolved in a few minutes, or in 1 to 2 hours, leaving the tubes clear. Maximum flocculation occurred in the tubes containing the third, fourth and fifth dilutions. It is possible that this phenomenon is due to the high concentration of albumin in the first and second tubes which exerts a 'protective effect' and prevents the flocculation of the colloidal mercuric oxide. The phenomenon is probably analogous to the zone phenomenon in the Widal test.

The normal albumin-globulin ratio of the blood serum is stated to be 2 : 1, and when this ratio is reversed or altered, a positive Takata-Ara reaction is said to occur. Nevertheless, the test may be completely negative while there is an increase in the globulin fraction or a decrease in the albumin fraction (Hassan and Salah, 1939). Jezler states that in his series of cases

TABLE VI

Takata-Ara reaction	KAHN			WASSERMANN		
	Negative	Weak positive	Strong positive	Negative	Weak positive	Strong positive
Strong positive (22 cases) ..	12	1	1	5	1	2
Moderate positive (7 cases) ..	4	1	1	1
Weak positive (3 cases) ..	1	..	1	1
Doubtful (1 case)	1
Negative (49 cases) ..	17	3	4	14	3	8
TOTAL (82 cases) ..	34	5	6	19	5	13

of positive reactions, the percentage of globulin to the total serum protein was higher than 55, whereas in the negative cases the percentage of globulin to total serum protein was about 37. Ragins, however, points out that, in his cases of positive reactions, the percentage of globulin was less than 37. In my series, out of four positive cases, only one gave a globulin percentage of 40. The other three gave percentages of 23.1, 11, and 11, respectively. Two negative cases gave globulin percentages of 43.5 and 55. It is, therefore, obvious from these contradictory observations that the chemistry involved in the reaction is obscure. It is probable that the reaction depends upon a qualitative change in the nature of the globulin.

Conclusions

According to Ragins, the reaction is positive in 98 per cent of cases of hepatic cirrhosis. 'That this reaction is of value in decompensated liver conditions due to cirrhosis is beyond doubt. For latent liver damage, the test is not entirely reliable'. He also tried the test in various other conditions such as renal and cardiovascular diseases. In the great majority, they were negative except in cases where liver insufficiency was co-existent.

In my series of 51 cases of hepatic cirrhosis, only four gave a negative reaction. The other 47 (92.2 per cent) gave a positive result. As mentioned previously, six other cases (four cases in the second group and cases 21 and 107 in the third group) in which evidence of liver damage was present, gave a positive reaction. There is, therefore, some evidence that a positive result is indicative of deranged liver function.

The practical utility of the test.—In cases of undoubtedly hepatic cirrhosis, where there is 'failure of compensation' as indicated by ascites and other symptoms, the test is not of much value from the prognostic point of view, but when there is no ascites or other evidence of 'decompensation' the test may be of value in detecting cases of cirrhosis in the early stages, when energetic treatment may be applied.

Summary

1. The Takata-Ara reaction has been performed in 117 cases including 51 cases of hepatic cirrhosis; only four of these 51 cases gave a negative reaction.

2. In six other cases where there was evidence of liver damage, the test was positive. The test is therefore of value in the diagnosis and prognosis of hepatic cirrhosis and hepatic insufficiency.

3. Out of 55 control cases only seven gave positive results, but two of these showed evidence of liver damage. In the other five, liver damage cannot be totally excluded, as no clinical details are available.

4. The technique of the test is described. Its simplicity warrants its extensive use in hospitals and laboratories.

5. There is no definite evidence that the test depends upon an increase of the globulin in the blood serum or ascitic fluid. The chemistry of the reaction is still obscure.

6. There is no striking relationship between the Takata-Ara reaction and the gel test. The Takata-Ara reaction has no relationship to the Kahn and Wassermann tests.

Acknowledgments

I am grateful to Lieut.-Colonel H. E. Shortt, Director, King Institute, Guindy, for helpful suggestions and criticisms in the preparation of this paper, and to Dr. C. G. Pandit, Acting Director, King Institute, for facilities provided in this investigation. Thanks are also due to the staff of the King Institute for their assistance. I am also grateful to Dr. K. Narayana-murti, honorary physician, Government General Hospital, Madras, and the other medical officers of the Government General Hospital, and other hospitals in the city and *mofussil* for their co-operation and assistance. I am also thankful to the superintendent, Government General Hospital, Madras, for providing me with all facilities in this investigation.

PROTHROMBIN TIME IN HEALTH AND
DISEASE*

(ACCORDING TO QUICK'S METHOD)

By D. V. S. REDDY

and

C. VENKATARAMIAH

Department of Physiology, Andhra Medical College,
Vizagapatam

RECENT advances in basic sciences supply a satisfactory explanation of the defects in the mechanism of coagulation of blood and suggest valuable methods for the laboratory diagnosis and therapeutic control of some of the most baffling clinical conditions, namely, haemorrhagic diseases.

Recent advances in physiology

Dam (1934; 1935) observed that chicks on synthetic diets developed haemorrhages uncontrollable by vitamins A, C and D. He therefore attributed the bleeding tendency to lack of a specific food factor, vitamin K (coagulation vitamin). Dam and Schonheyder (1934) demonstrated that the delay in coagulation in chicks on diets deficient in vitamin K was not caused by a disturbance in the levels of fibrinogen, calcium or the cellular elements of the blood or the thrombokinase of the tissues. Dam, Schonheyder and Tage-Hansen (1936) subsequently showed the element deficient in the blood of these chicks to be prothrombin.

Investigations along a different line have thrown new and valuable light on the significance of the above researches. Numerous studies relating to the coagulation defect in jaundice had revealed that bleeding in jaundice was not due to a disturbance in fibrinogen, calcium, or formed elements, or in any other easily studied component of clotting mechanism. Only one component in blood, prothrombin, remained to be still investigated. Quick (1935; 1937; 1938) devised a method, simple but specific, to determine blood prothrombin and also succeeded in demonstrating a prothrombin deficiency in

jaundiced patients with haemorrhagic tendency. Warner, Brinkhous and Smith (1936) have developed a more accurate but somewhat complicated method. Recently, a third method has been employed and advocated by Dam and Glavind (1938; 1940).

Two interesting findings are disclosed by the above studies. The first is that the prothrombin level is constant for each species. The second is that ordinarily the level of prothrombin is much in excess of the physiologic requirements, providing for large losses. Serious haemorrhages do not occur until 80 per cent of prothrombin is lost and the blood prothrombin sinks below 20 per cent.

With the aid of these newer methods for the determination of prothrombin, it has become possible to gain further information regarding the stages in the synthesis of prothrombin by suitable experimental procedures on animals and by investigation of clinical conditions, with frank haemorrhages or in suspected cases of haemorrhagic diathesis.

Hypoprothrombinæmia produced by surgical procedures in animals

(A) *Biliary fistula*.—Dogs with bile fistula develop spontaneous haemorrhages. Greaves and Schmidt (1937) demonstrated that prothrombin could be markedly lowered by either ligation of bile duct or by making a biliary fistula. They also observed a haemorrhagic tendency in rats with bile fistulae. These animals had a low level of prothrombin by Quick's method. Bile is necessary for the adequate absorption of fat-soluble vitamins. Absence of bile in the intestine leads to impaired absorption of vitamin K with resulting lowering of plasma prothrombin. Both the hypoprothrombinæmia and haemorrhages were quickly controlled by administering adequate amounts of bile salts along with the usual diets.

(B) *Experimental liver damage*.—Smith, Warner and Brinkhous (1937) reported a marked drop in blood prothrombin in dogs subjected to prolonged chloroform anaesthesia. Partial hepatectomy also reduced the prothrombin level. Total hepatectomy in dogs and rats was followed by a rapid decline of prothrombin. In rabbits, a haemorrhagic tendency was observed after artificially produced fever (severe hepatic necrosis?).

In view of these findings, it may be concluded that liver is essential for the formation of prothrombin and that the concentration of prothrombin is reduced in all conditions with extensive parenchymatous damage to the liver. It is also assumed that the liver is concerned in the conversion of vitamin K (derived from diet or from the action of intestinal bacteria) into prothrombin. In the jaundiced patient, the reduction of prothrombin may be due either to inadequate absorption from the bowel or faulty utilization by the damaged liver or to a combination of both defects.

The purpose and programme of this work may be said to be threefold—

(1) The choice of a suitable method for the study of the anomalies of coagulation and haemorrhagic diseases.

(2) The determination of prothrombin time in normal healthy adults.

(3) Observations on the variations in prothrombin time in various diseases.

Choice of the method or technique

In order to select an accurate, widely-used and well-established technique, a good deal of time was spent in wading through the extensive and rapidly increasing literature on the various laboratory procedures found useful in the study of the defects of coagulation and haemorrhagic diathesis. Local conditions, laboratory facilities at our disposal, and the growing handicaps due to the difficulties in obtaining new apparatus and new chemicals, imposed severe restrictions on our choice. We had reluctantly to abandon all hope of starting work on the very accurate method of Warner, Brinkhous and Smith and even on the simpler method advocated by Dam and Glavind. After reviewing our present facilities and taking account of the future uncertainties, we decided to study the possibility of using Quick's method in our work. It is now well recognized that patients whose coagulation time and bleeding time is normal, as judged by the usual tests, may still develop haemorrhages, particularly those with jaundice and biliary tract disease. It is in such cases that the new test devised by Quick reveals a potential impairment of clotting and gives a danger-signal warning against the possibility, nay probability of haemorrhages. Quick's method is therefore a definite improvement over the older methods now in use in the hospitals and laboratories.

The principle and technique of Quick's test

The method is based on the assumptions that the rate of coagulation is a function of the concentration of thrombin and that the production of thrombin in oxalated plasma is proportional to the concentration of prothrombin, if an excess of thromboplastin is present and an optimum amount of calcium is added. The clotting time according to this method is a direct measure of prothrombin content.

Four and a half cubic centimetres of blood obtained by venepuncture is mixed immediately with 0.5 c.cm. of M/10 sodium oxalate solution and centrifuged. 0.1 c.cm. of plasma is pipetted into a clean dry test-tube and is mixed with 0.1 c.cm. of thromboplastin solution prepared according to Quick's directions. The test-tube is kept immersed in a water-bath at 37°C. for a few minutes and then 0.1 c.cm. of M/40 solution of pure anhydrous calcium chloride is quickly added. The contents of the tube are now rapidly shaken while immersed in the bath for a few more seconds. The test-tube is now removed from the bath and rocked gently, at

short intervals, until the mixture is seen to coagulate. The time in seconds (accurately recorded with a stop watch) from the time of adding calcium to the moment of coagulation constitutes prothrombin time.

Whenever a new specimen of thrombokinase is prepared and whenever new solutions are made, the prothrombin time of normal controls is estimated for purposes of comparison.

Quick's method was slightly modified by Illingworth (1939). The general procedure is the same as above but the source and quantity of material used to prepare the emulsion of thrombokinase differ. Quick prepared the thrombokinase from rabbit's brain by macerating the brain with acetone, while Illingworth uses human brain tissue from the autopsy room. After removal of the meninges and vessels, the brain is thoroughly washed to remove all blood and is pulped and ground into a uniform paste. It is then spread as a thin layer over a sheet of glass and dried by an electric hot-air blower. The dried brain is scraped off and stored in a well-stoppered bottle. Before use, 2 grammes of the dried brain is emulsified in 10 c.cm. of physiological saline and incubated for 15 minutes at 37°C. After this, it is filtered through gauze to remove coarse fragments.

In our early studies, we followed Quick's original method; later, as acetone was not available locally, we followed Illingworth's modification.

Prothrombin time in normal healthy adults

In our observations on 20 adults, using Illingworth's technique, we obtained prothrombin times ranging between 15 and 25 seconds (see table). In an earlier series, where

TABLE I*
Prothrombin time with M/40 calcium chloride solution

Number of cases	Nature of disease	Ages: years	PROTHROMBIN TIME IN SECONDS		
			Range	Mean	S.D.
20	Normals, and non-hepatic conditions.	15 to 40	14 to 25	19.2	± 2.8
1	Jaundice	25	..	45.0	..

TABLE II*
Prothrombin time with M/10 calcium chloride solution

Number of cases	Nature of disease	Ages: years	PROTHROMBIN TIME IN SECONDS		
			Range	Mean	S.D.
20	Normals or non-hepatic diseases.	15 to 55	41 to 65	53.1	± 7.6

* Summarized by Editor.

thrombokinase from rabbit's brain was used, we noticed that the prothrombin times were two to three times longer than in Quick's experience. The prothrombin times of 24 adults with no recognizable disease of the liver or of blood were between 40 and 60 seconds (table II). This undue prolongation of clotting time, we later found to be due to the fact that the calcium solution used in this early series was made by dissolving 1.11 grammes in 100 c.cm. of distilled water as mentioned by Quick (1938). This figure is obviously a wrong one*, as Quick and other workers, using the same method, mention repeatedly that a M/40 solution of calcium is to be used. Such a solution is prepared by dissolving 0.2775 gramme in 100 c.cm. of distilled water. Tests repeated with M/40 solution gave a prothrombin time of 15 to 25 seconds.

Prothrombin in various clinical conditions

With the kind co-operation of the staff of the King George Hospital, a number of patients from the out-patient as well as in-patient departments were examined for prothrombin time. Patients with skin diseases, patients with even surgical conditions (like carbuncle neck, iliac abscess, vesical calculus) or patients with medical complaints (like lumbago, lymphadenitis, peripheral neuritis, chronic arthritis and round worms) did not show any definite and significant alterations from the normal. The only cases which gave prolonged prothrombin time were those suffering either from severe jaundice or cirrhosis of the liver. One patient with jaundice has been diagnosed as cancer of the stomach with large multiple deposits in the liver. These cases came into the hospital in the early days of our observations when the normal adults gave a prothrombin time ranging between 40 to 60 seconds. Two patients with obstructive jaundice and two with cirrhosis of the liver gave prothrombin times ranging between $2\frac{1}{2}$ minutes and 3 minutes (see table III). As far as we have been able to ascertain, none of these four patients had so far manifested any tendency to bleeding.

Determination of prothrombin time with the improved dilution technique, on similar cases and on other types of cases, is being continued. Further, work is also in progress to prepare a chart like that of Quick indicating the relation of clotting time to the concentration of prothrombin, with ultimate object of providing clinicians with a ready and convenient scale to estimate the risk of haemorrhage in any patient.

* In a private communication, Quick has pointed out that this was a printing error; 100 c.cm. should have read 400 c.cm.

[Note.—Napier and Das Gupta (*Indian Med. Gaz.*, 76, 229) copied this wrong figure into their paper, but these writers have actually been using a weaker solution of calcium chloride, and they now confirm the present writers' observation that more accurate results are obtained with M/40 solution.—EDITOR, I. M. G.]

TABLE III
Prothrombin time in clinical conditions, with
M/10 calcium chloride solution

Number	Age	HEALTHY MEDICAL STUDENT SHOWED A PROTHROMBIN TIME OF 57 SECONDS	
		Disease	Prothrombin time in seconds
1	25	Jaundice	165
2	40	Cirrhosis of the liver	169
3	50	Do.	150
4	35	Jaundice—cancer liver	140
5	40	Enteric fever 19th day (bloody motions on the 17th day).	85
6	30	Peripheral neuritis	52
7	50	Ing. hernia	50
8	30	Iliac abscess	75
9	22	Vesical calculus	67
10	57	Carbuncle neck	76

Control.

The last four were pre-operative cases.

Summary

1. Prothrombin time of a number of healthy adults was determined according to Quick's method. In the earlier series when M/10 calcium chloride solution was used the time ranged between 40 and 60 seconds. In the second series where M/40 calcium chloride was used the time ranged between 15 and 20 seconds.

2. Prothrombin time was markedly prolonged in cases of obstructive jaundice and cirrhosis of the liver. It was more than $2\frac{1}{2}$ minutes when the normals gave a prothrombin time of 40 to 60 seconds, and 45 seconds when the controls gave a prothrombin time of 15 to 25 seconds.

3. The prothrombin time was normal in subjects with certain complaints (warts, gonorrhœa, lumbago, enlarged lymph glands and ophthalmic conditions).

4. Prothrombin time was slightly prolonged in a case of carbuncle, in iliac abscess, enteric fever, periostitis, secondary syphilis with rash, etc.

5. Recent improvements in the technique of the test, using serial dilutions, may bring out more definitely minor degrees of prothrombin deficiency in cases of malnutrition involving subclinical multiple vitamin deficiency, and in medical and surgical conditions, specially common in the tropics.

Acknowledgments.—We are greatly indebted to the members of the staff of the King George Hospital, Vizagapatam, for their co-operation in carrying out these investigations and to Mr. Krishnamurty, Lecturer in Chemistry, Andhra Medical College, for help in laboratory work. We are grateful to Dr. Alahasingari, Professor of Physiology, for his interest in the progress of this work and for some valuable suggestions.

Medical journals received in India during the last three months (and after the completion of this paper) contain many articles dealing with further work on the subject. Three important lines of development deserve to be specially noticed:

1. Allen, Julian and Dragstedt (1940) advocate a modified one-stage technique using serial dilutions in the determination of prothrombin. The authors refer to the advantage of serial dilution in cases in which prothrombin response to vitamin K is minimal or sluggish. They conclude that the more dilute plasmas more readily reflect minor changes in the clotting time.

2. Souter and Kark (1940) prepared a stable thromboplastin by utilizing the method of 'lyophilization', thus avoiding the rather laborious and time-consuming processes involved according to Quick. The thromboplastic reagent for the test could be readily and easily obtained for immediate use by the addition of distilled water alone.

Fullerton (1940) dispenses with the elaborate method of preparing the thromboplastic substance from brain or other tissues and used Stypven solution (0.1 gm. of venom being dissolved in 1 c.c.m. of distilled water). In working with serial dilutions, he noticed that the end point could be more easily determined when Stypven is used than with emulsions of tissue extracts. Hobson and Witts (1940) however point out, in a preliminary communication, that snake venom must be supplemented with lecithin, and promise a full account of their experiments in the near future. They employed Rusven (Boots).

3. Fitzgerald and Webster (1940) record their observations with a bed-side test. They prepare three 'Quick's' method. 0.1 c.c.m. of blood to be tested is placed in a small test-tube, the blood to be tested is added to make up 1 c.c.m. Clotting time is noted and compared with the clotting time of normal blood. The authors recommend this test for ward work.

THE STERILITY AND POTENCY OF INJECTABLE SUBSTANCES

(iii) CHOLERA VACCINES

By C. L. PASRICHA

MAJOR, I.M.S.

Professor of Bacteriology and Pathology

Z. ABEDIN

and

B. M. PAUL

*(From the Department of Bacteriology and Pathology,
School of Tropical Medicine, Calcutta)*

PASRICHA *et al.* (1938) recorded the results of the examination of fourteen cholera vaccines. The vaccines were tested for sterility, freedom from abnormal toxicity, antigenic response in rabbit and man, and protective value in guinea-pigs. It was found that whereas the six cholera vaccines prepared by recognized laboratories gave satisfactory antigenic response and protected guinea-pigs against two M.L.D. of *Vibrio cholerae*, only four of the eight commercial preparations produced cholera agglutinins and four vaccines gave uniformly negative results. It was further shown that the comparatively simple test of direct agglutination gave valuable information as to the antigenic structure of the organism used in the preparation of the vaccine, and that the results obtained by direct agglutination test corresponded closely to the results of the more costly and time-consuming agglutinogenic test in animals.

A further series of 200 samples of cholera vaccines have been tested with the following results :—

Number of vaccines that did not pass the sterility test—68 or 34 per cent.

Number of vaccines that were not satisfactory by the direct agglutination test—102 or 51 per cent.

Number of vaccines that passed both the sterility and potency tests—74 or 37 per cent.

The opacity of each vaccine was compared with Brown's opacity tubes and controlled with a vaccine made in the laboratory and stored for different periods so that the test vaccine was compared with a control vaccine of approximately the same age. The opacity of the different samples varied considerably; some were very thick suspensions (corresponding to about 16,000 millions per c.c.m. or even more, to others which were so light that the opacity could not be estimated). All samples were claimed to contain 8,000 million organisms per c.c.m. The final readings were made by comparing with Brown's opacity tubes 1 to 4, and, if the vaccine was more opaque than tube 4, the vaccine was diluted so that the diluted suspension came

(Continued from previous column)

SOUTER, A. W., and KARK, *Amer. J. Med. Sci.*, **200**, 603.
R. (1940).

WARNER, E. D., BRINK-
HOUS, K. M., and
SMITH, H. P. (1938).

within the range of tubes 1 to 4. The strength of the original suspension was calculated by multiplying with the dilution factor. The results of the opacity tests are summarized below:—

TABLE

Showing the opacity of 200 samples of cholera vaccines

Opacity in millions per c.c.m.	Number of samples	Percentage of samples
1,093 or less	24	12
2,185	46	23
3,278	48	24
4,370	20	10
6,556	14	7
8,740	16	8
13,152 or more	32	16

Even after allowing for the autolysis which is known to occur, it is unlikely that the 70 samples of cholera vaccines which showed an opacity of 2,185 millions per c.c.m. or less originally contained the 8,000 million organisms that they were claimed to contain. The finding of considerable excess of organisms in 32 (16 per cent) of the samples suggests that adequate control of the suspensions is not maintained during manufacture. This is a point that should be and can be easily controlled by the manufacturers of cholera vaccines.

In order to overcome the difficulty of autolysis that occurs in vaccines, a thick suspension of *V. cholerae* was desiccated and sealed under vacuum. The desiccated vaccine re-suspends readily in saline and there is no appreciable loss in opacity during storage. There is the additional advantage of considerable saving of space with desiccated vaccines, and, from the results obtained so far, there are indications that the vibrio antigens are better preserved in the desiccated state than in liquid suspensions, a conclusion which is supported by a considerable volume of published data on the preservation of other biological material. The method of desiccation is comparatively simple and offers great advantages, particularly in this country where there are great difficulties of adequate storage and transport.

Summary

The results of the examination (for sterility and potency) of a series of 200 cholera vaccines are recorded. Sixty-eight, or 34 per cent, did not pass the sterility test and 102, or 51 per cent, were not satisfactory by the direct agglutination test. Seventy-four, or 37 per cent, of the 200 samples passed both the sterility and potency tests.

The opacity of the cholera vaccines varied considerably; some suspensions were too thick, containing approximately twice the amount of organisms that they were said to contain, whilst others were so light that the opacity could not be

HYPOCHLORÆMIA IN CHOLERA

By D. N. BANERJEE, M.B. (Cal.), M.D. (Berlin)
Officer-in-Charge, Cholera Kidney Enquiry, I. R. F. A.;
Lecturer in Pathology, Carmichael Medical College,
Calcutta

THE rôle of deficiency of chloride in the blood as a factor leading to disturbances of renal function has been known for a long time. It has further been observed that hypochloræmia, whatever the cause, produces a train of manifestations more or less similar in all circumstances.
